THE DE KEATING-HART METHOD OF FULGURATION.*

By WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D.,

NEW YORK.

One of the world's greatest philosophers has said: "There is a principle which is a bar against all information, and which cannot fail to keep a man in everlasting ignorance; this principle is contempt prior to examination." It is the desire of every seeker after truth to avoid this deadly principle, to examine first, and then to accept with approval, or to reject with contempt. If examination is impossible, suspended judgment is in order.

The Committee on Scientific Research of the New York Skin and Cancer Hospital has borne this principle in mind in its study of the cancer problem, being willing at all times to investigate the claims of any method for the palliation or cure of malignant neoplasms, providing, of course, that such investigation present no element of danger to the well-being of the patients concerned.

Accordingly, when, about five years ago, our attention was first directed to the treatment of cancer by the de Keating-Hart method of "fulguration," or "sideration," as it was then called, it was decided to investigate the theory upon which the method was based, as well as the technic of its application, and, if results warranted it, to give the method a scientific trial in a series of cases.

As the representative of the New York Skin and Cancer Hospital, and as a surgeon greatly interested in the cancer problem, the author, on various trips to Europe, visited de Keating-Hart, who demonstrated his apparatus and explained his method in detail. I saw him employ fulguration in numbers of cases, and examined many of the patients previous to operation, as well as upon successive visits afterward. Dr. de Keating-Hart has been kind enough to furnish us with photographs and lantern-slide pictures of a number of patients treated by him from time to time, many of whom I have examined at his clinic in Paris. A few of these photographs will serve to convince the reader, as the actual cases did me, that the method is worthy of careful trial.

Fig. 1.

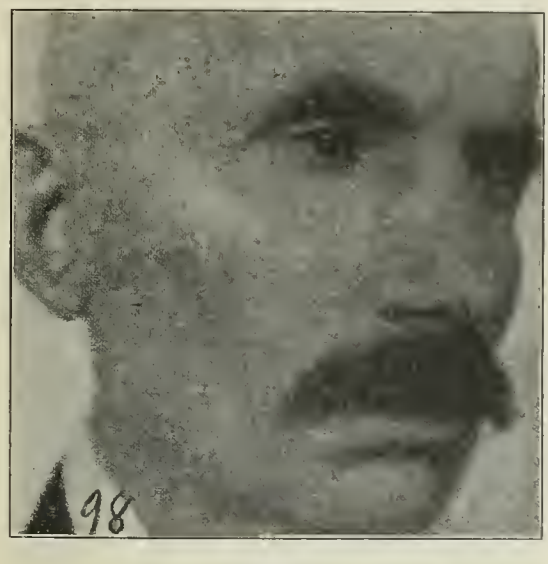

Fig. 2.

Case I.—Epithelioma of the right side of the nose, which had invaded the subjacent bone. The first fulguration in 1907, the second in January, 1908, and the third in December, 1908. This patient having refused to submit to an anesthetic, it was impossible to treat him thoroughly at a single sitting. Cured for three years. (See Figs. 1 and 2.)

In some of the cases the cure of the cancer does not offer in itself any special interest, since this might have been obtained, as de Keating-Hart has pointed out, by a number of well-known means in at least the first group. The cases are of real significance only when considered from a triple point of view, which should be borne in mind as the pictures and the case histories are studied:

(1) The strictly limited eradication of tissue

*Read in part before the New England Association of Physical Therapeutics, Boston, April 12, 1912. Illustrated with lantern slides. Delivered in part, with the presentation of patients, at the Eighth Annual Clinical Lecture on Cancer, New York Skin and Cancer Hospital, April 24, 1912.

around the lesions, thus saving or lessening subsequent deformity.

(2) The non-recurrence obtained for a number of years, although in certain cases the disease had not been checked by other means; or, in primary cases, the lessened likelihood of recurrence.

(3) The relatively slight disfigurement produced by the method in the cases presented.

These cases are all a matter of record, and are reproduced here merely for purposes of interest and emphasis. It may be said, in justice to de Keating-Hart and his method, that these cases represent patients of sufficiently various age and disease of sufficient severity to give to them an undeniable value. Each has undergone careful histological examination, and in the published works of de Keating-Hart may be found the names of physicians and surgeons by whom the patients were treated, as well as the names of the laboratories where microscopic examinations were made.

The cases herein described or pictured have been selected for this paper by Dr. de Keating-Hart as best illustrating his methods.

Superficial Cancers of Cutaneous Origin (Cases I to VI).—The first group represents superficial cancers of cutaneous origin, which are interesting in that they show what excellent cosmetic results fulguration may give.

Fig. 3.

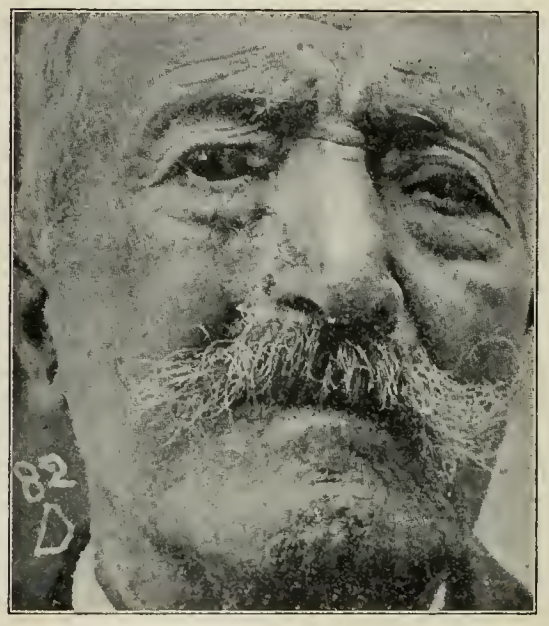

Fig. 4.

Case II.—Epithelioma of the squamous celled type involving the inner canthus of the right eye and the nasal process of the superior maxilla. Fulguration December 31, 1907. Was seen again three years later. Cured.

Fig. 5.

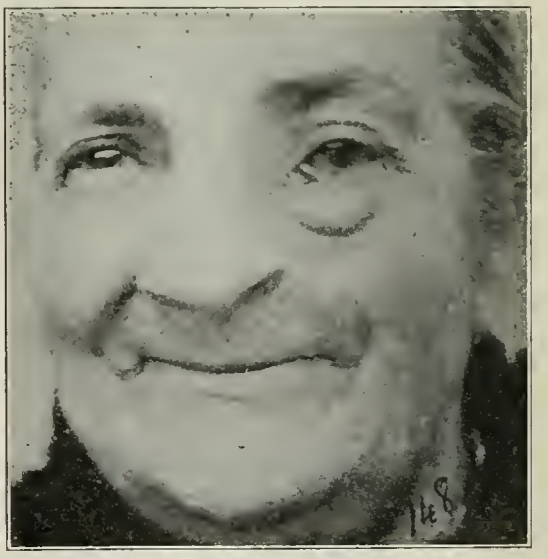

Fig. 6.

Case III.—Epithelioma of the skin of the superior maxilla and of the bones of the nose. Treated without success by arsenical cauterization. Fulguration February 14, 1908. Seen again a year and a half later. Cured. (See Figs. 5 and 6.) I have heard since that she had a recurrence. This is possible. The case was very severe and the removal without doubt insufficient, but I cite the case especially because of the cosmetic result. [de Keating-Hart.]

Deep Cancers of Cutaneous Origin (Cases VII to XI).—The next group represents deep cancers of cutaneous origin, which have acquired a greater severity from the fact of their extent and their penetration into the subjacent osseous tissue. Here the cosmetic effect is less than the therapeutic effect, but is nevertheless not entirely wanting. It is well to note that most of these cases were considered inoperable and that some had been unsuccessfully treated by other methods.

Cancers of the Breast (Cases XII to XV).—The following cases of cancer of the breast are presented, not only because of their severity, but because of the limited removal of diseased tissue, in spite of which permanent results were obtained. It is to be emphasized, in this connection, that this limited removal of tissue is not advocated by de Keating-Hart and others who have employed the method, except in cases where more extensive removal is not feasible.

Cancer of the Cervical Region (Case XVI).

Cancers of the Mucosa (Cases XVII to XX).

Fig. 7.

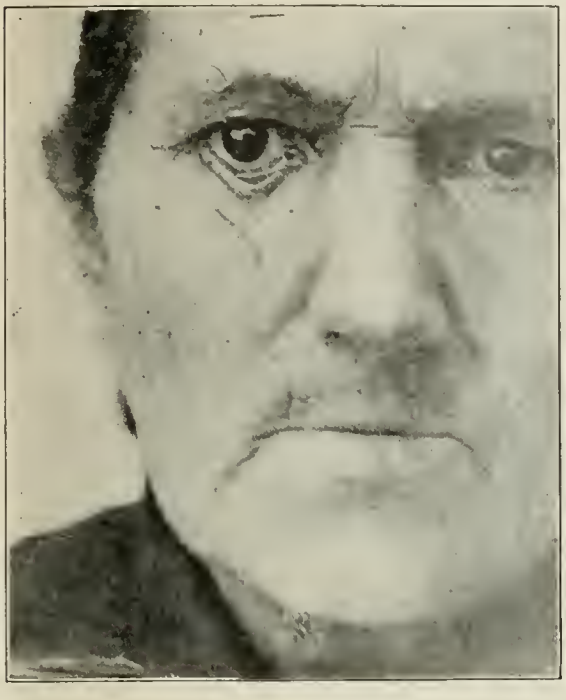

Fig. 8.

Case IV.—Epithelioma of the face. Treated previously by surgery and *x*-rays with immediate and severe recurrence. Fulguration carried out August 29, 1907. Was followed in twenty days by a beautiful cicatrization, as shown in the figure. The patient has glands in the neck which were not fulgurated (unfortunately) which naturally have increased in size, but the local healing is still present. (See Figs. 7 and 8.)

Fig. 9.

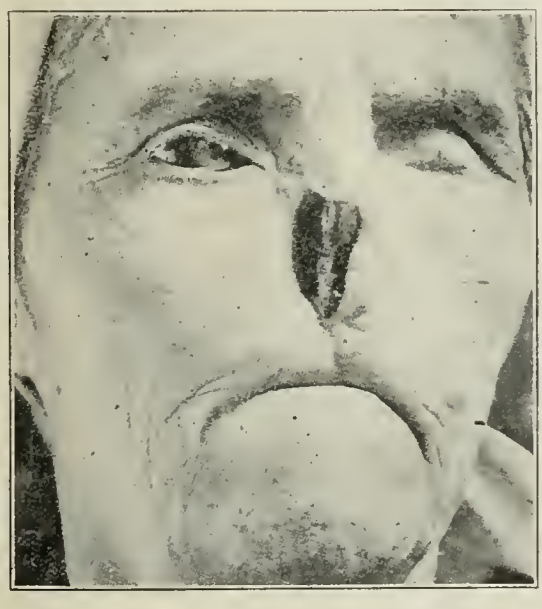

Fig. 10.

Case V.—Flat epithelioma of the face extending to the mucous membrane of the upper lip and to the nose. Rapid growth. Fulguration June 6, 1908, preceded by very limited removal of the growth. (Lost to sight a short time afterward.)

—De Keating-Hart claims to have obtained a number of permanent results in cases of cancer of the lip in which there was limited removal of the lesion, without removal of the diseased glands. These cases demonstrate the favorable results of fulguration even with incomplete removal of the disease.

Fig. 11.

Fig. 12.

Case VI.—Ulcerating and proliferating epithelioma at the inner angle of the right eye and on the nose. Fulguration June 3, 1907, with simple curettage. Very neat healing in twenty days, continuing perfectly well for three years. (See Figs. 11 and 12.) Lost from sight since then.

Cancer of the Rectum, in severe cases, has given less favorable and less permanent results than has cancer in other parts of the body.

Cancer of the Uterus has not given good results with fulguration, according to de Keating-Hart. It is one of the localized forms of cancer where fulguration is least indicated, because of the possibility of the complete surgical removal of the disease. If the condition is inoperable fulguration may relieve and produce superficial cicatrization, but it will not cure.

Sarcomatous Tumors often show "splendid healing" from fulguration, according to de Keating-Hart.

As the months passed and de Keating-Hart's reports continued favorable, as did likewise those of a number of other European investigators, our interest was still further aroused in the method.

Desplat, appointed by the French Association for the Advancement of Science, to report upon "the remote results of fulguration in the treatment of cancer" (Congress at Toulouse, August, 1910), cited a number of interesting cases published by Dubois-Crepagne and himself. He concludes his report with the following: "After three years' experience, I conclude, as I concluded after the first year, that fulguration has enlarged considerably the field of surgery in giving it marked chance of success in those cases where it previously dared no longer intervene, and I now reply to the question which I had left under judgment for two years, that fulguration gives to the patient chances of prolonged non-recurrence superior to those chances which surgery gives when left to itself alone."

Segond, who declared himself, at the International Conference on Cancer, in Paris, in October, 1910, as being against the method, said of it, fulguration "has increased their resistance and prolonged their lives, transformed or cicatrized, in praiseworthy fashion, horrible, bleeding areas which tortured" patients whose pains nothing would calm. "Fulguration," he said, "permits surgery to intervene where intervention was no longer posible, and may offer a chance of non-recurrence to those cases which surgery alone cannot relieve."

Such statements, reinforced by our own observations, encouraged us, despite the unfavorable reports which from time to time appeared, to install a de Keating-Hart fulguration apparatus at the New York Skin and Cancer Hospital, and to extend to Dr. de Keating-Hart an invitation to visit New York and personally demonstrate the apparatus and explain the theories upon which his method of fulguration is based.

The apparatus, which had been constructed under de Keating-Hart's personal direction, was installed in the hospital in November, 1911, and in December he visited America, giving a series of demonstrations at the New York Skin and Cancer Hospital, and delivering a number of lectures in other cities. Invitations were extended to many of the leading surgeons in this country and Canada to attend these demonstrations, and the operating room was taxed to its utmost capacity each day by members of the medical profession who seemed eager to witness the fulguration "seances," as the originator of the method is wont to call the applications of fulguration.

Many cases of cancer, in various stages of operability, were treated during the nineteen days of Dr. de Keating-Hart's visit. The surgical operations were performed by myself, with the assistance of Dr. Franz Torek, Dr. E. M. Foote, and other members of the hospital staff. Dr. de Keating-Hart was assisted in the instrumentation by Dr. Worthington S. Russell, in charge of the electrotherapeutic department of the hospital.

On behalf of the New York Skin and Cancer Hospital, of the Committee on Scientific Research, and of myself personally, a formal expression of thanks is tendered Dr. de Keating-Hart for his willingness to leave his own work and to give such untiring energy to the demonstrations at the Skin and Cancer Hospital.

It is our intention to continue to employ the method in all suitable cases, as we have been doing since his visit. Careful records of each case are kept. Notes were made of the treatment to be fol-

lowed in each of the cases treated by de Keating-Hart, and his directions have been carried out in detail. At the end of a period of time sufficiently long to warrant forming a conclusion as to the merits of the procedure, a full account of our experience with fulguration will be published.

Fig. 13.

Fig. 14.

Case VII.—Large flat epithelioma of the antero-superior cranial region, with invasion of the frontal bone down to the diploë. There were two metastases in the pericranium. This case was considered inoperable by several surgeons. The first fulguration with curettage was done on January 6, 1907, in the presence of Dr. Saias of Marseilles. Cicatrization perfect. Recurrence at the end of one year. Two repeated fulgurations in 1908 and 1909. In perfect condition at time of report, about three years later. (See Figs. 13, 14, and 15.)

Other Electrotherapeutic Measures Often Confounded with Fulguration.

Before taking up the further discussion of fulguration and the theory upon which its application is based, attention will be called very briefly to some of the methods of employing high-frequency sparks which have been confounded in the minds of many with fulguration as employed by de Keating-Hart. It may be said, in passing, that this discussion is confined absolutely to fulguration as employed at the present time by de Keating-Hart, and that we shall in no wise enter into a discussion of the Rivière-de-Keating-Hart controversy, mentioned by so many writers on this phase of electrotherapeutics.

Fig. 15.

During the demonstration at the Skin and Cancer Hospital de Keating-Hart repeated over and over the statement that fulguration as employed by him is *not a burning method;* that it does *not destroy tissue,* normal or abnormal; that if it is applied to the extent of burning it is distinctly harmful, and is not then true fulguration; and that it acts, *not upon the cancer itself,* but upon the *soil upon which the cancer develops.*

Despite these statements it was not an uncommon thing to hear visitors tell of their experience with fulguration in the destruction of neoplasms, of "burning down" this or that kind of growth, and of using short sparks, bipolar currents, and other details diametrically opposed to the de Keating-Hart method.

It may be interesting in this connection to cite a passage from the 1911 edition of one of the leading text-books on electrotherapeutics.* "The application of high frequency discharge," says the author of this volume, "from a metal point with a current of sufficient energy to destroy living tissue, was first described and instituted by Dr. J. A. Rivière of Paris, France. He employed the method for the destruction of epitheliomata, warts, moles, and condylomata. His student, Keating-Hart, employing the same method in connection with the operative treatment of cancer of the breast, with a view to preventing secondary recurrence by following the knife with the application of the same method designated the process as 'fulguration,' giving the original investigator no credit for the originality of the method. His association as a surgeon led to the adoption of the latter name which is the designa-

*Snow, William Benham: "Currents of High and Other Potential of High and Other Frequencies."

tion of the effect and not the method; the method being a hot effleuve discharge and the effect one which simulates burning."

"The process of effleuvation," he continues, "may be applied for a cauterant effect or as a desiccating agent as described by Clark; the discharges in the one case destroying the tissue by actual chemical decomposition of heat, and the other process by applying the current with sufficient strength to produce a drying out of the tissues with the induction of coagulation-necrosis. When the thermic application is made in the tissues, above 73° C., coagulation-necrosis is induced."

After witnessing a number of de Keating-Hart's demonstrations at the New York Skin and Cancer Hospital, the author above quoted said, in an article

Fig. 16.

Fig. 17.

Case VIII.—Epithelioma of the nose; rapid growth with marked involvement of the bones. Curettage and fulguration December 3, 1907. The patient had been previously treated without success by the actual cautery. Very excellent healing; well three years later.

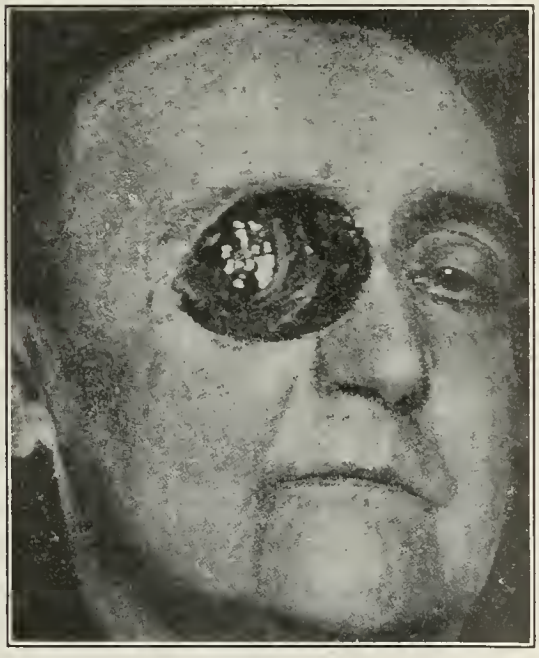

Fig. 18.

Fig. 19.

Case IX.—Deep epithelioma of the orbital region. Considered by all surgeons consulted as absolutely inoperable. Destruction of the eye and invasion of the ethmoid bone. Fulguration in December, 1907. No recurrence for nearly three years. Perfect return of the general health, which had been undermined by the terrible pain and the use of morphine. (See Figs. 18 and 19.)

in the *Journal of Advanced Therapeutics* for January, 1912, "The principle employed by him (de Keating-Hart) is to remove entirely the cancerous growth, and then to appply to the surfaces and tissues from which the cancer has been removed long, high potential resonator sparks, in quality very similar to the sparks from a static machine. This administration gives no burning or destruction of tissues, but an effect of over-stimulation which, according to the theory of de Keating-Hart, depletes or exhausts the tissue to such a degree that the reparative process is considerably deferred, the effect from the application of the electrical sparks lowering the vitality of the normal cells, and destroying by depletion the diseased cells that may have been left in the tissues."

Fig. 20.

Fig. 21.

Case X.—Epithelioma with invasion and destruction of the left eye, the malar bone, and a portion of the superior maxilla. Fulguration June 29, 1908. Cured for three and one-half years. A fistula communicating with the nose still persists. (See Figs. 20 and 21.)

Fig. 22.

Fig. 23.

Case XI.—Orbital epithelioma. Invasion of the left eye, the superior maxilla, and the bones of the nose. The patient was sent by Prof. Lapersonne to Prof. J. L. Faure, who operated before using fulguration on February 4, 1909. Cured for nearly three years. Patient was presented by Dr. J. L. Faure before the Surgical Society. (See Figs. 22 and 23.)

Another distinguished writer on electrotherapeutics,* in 1910, said of the method under dis-

*Tousey, Sinclair: "Medical Electricity and Röntgen Rays."

cussion: "This method consists in the application of long and powerful sparks for the destruction of morbid tissue. The apparatus may be any of the resonators giving high-frequency currents, and may be either monopolar or bipolar, the latter being preferable."

From the above it will be seen how easily the fulguration of de Keating-Hart may be confused with the "destructive fulguration" to which various writers allude.

Fig. 24.

Fig. 25.

Case XII.—Epithelioma of the nipple of rapid growth. Examination showed an indurated mass of the size of a walnut. Fulguration May 12, 1908, with excision passing exactly around the lesion, thus forming a cone shaped area in the breast. Still cured after three and one-half years. (See Figs. 24 and 25.)

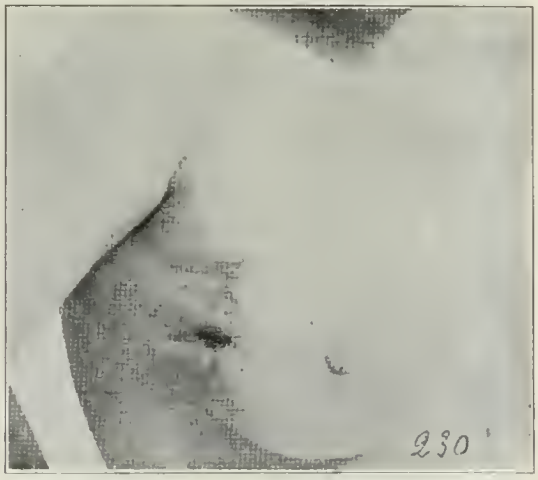

Fig. 26.

Fig. 27.

Case XIII.—Epithelioma of the right breast, occupying the superior external quadrant. Rapid growth of the tumor to the size of a pear. No glands were felt. Fulguration July 9, 1908. Removal of the lesion only and conservation of the greater part of the breast. No recurrence after two years. Disappeared from observation. (See Figs. 26 and 27.)

The term "fulguration" (lightning) was suggested by Pozzi, and soon supplanted the term "sideration" (a sort of stunning of cancer cells), which de Keating-Hart at first applied to his method under a mistaken conception of the action of the spark upon the neoplasm.

The fulguration of de Keating-Hart, the "destructive fulguration" obtained with short sparks, desiccation, electrocauterization, electrocoagulation (Doyen), "diathermy" (Nagelschmidt), all signify the application of currents of high frequency. The current, however, may be unipolar or bipolar, and the spark may be long or short, or suppressed, and herein is the difference between the de Keating-Hart fulguration and the various methods of electrothermic penetration.

In fulguration the unipolar current, with long, high-frequency, high-tension sparks, is employed.

In the other methods named, the bipolar current is generally employed, though in some the unipolar current may be used. In the former the amperage is comparatively low and the voltage high, which its application is carried, giving the respective designations to the different methods. Fulguration, on the other hand, is in no sense a destroyer of tissue, but a *modifier of trophic nerve centers.* It is

Fig. 28.

Fig. 29.

Case XIV.—Conservative intervention. Cicatrization of cancerous breast after limited removal. Cancer following Paget's disease. The left mammary gland deeply invaded. Enlargement of glands in the axilla. In view of the great age of the patient, seventy-six years, and her feebleness, decided to remove only the diseased part of the breast. Operation performed in the service of Prof. Tuffier of Paris. Still cured after three and one-half years. (See Figs. 28 and 29.)

Fig. 30.

Fig. 31.

Case XV.—Epithelioma of the left breast. Operated twice, with recurrence on the ribs, in the axilla, and in the skin of the flank and shoulder. Patient had received radium treatment which ameliorated her condition somewhat. At the time of fulguration there was cachexia, swollen arm, and intense pain. Fulguration in March, 1906, and in February, 1907. Incomplete excision of the nodules and of the axillary mass by Prof. Maurras of the Colonial Infantry. Remained in perfect health for more than three years. I do not know if this will continue, as one must expect a recurrence, since there was still some diseased tissue left in place which it was impossible to remove, but it is extraordinary to have been able to obtain such a result in such a case [de Keating-Hart]. (See Figs. 30 and 31.)

while in the latter the reverse is usually the case.

Desiccation, "diathermy," electrocoagulation, etc., are all methods of *electrothermic destruction of tissue,* the strength of the spark and the extent to understood, of course, that these are de Keating-Hart's opinions.

It is not necessary for the purpose of this communication to go into further details concerning

the various methods named. It may be said, however, that apparatus for employing these have been installed in the New York Skin and Cancer Hospital, and the relative merits of the different methods will be thoroughly tested in suitable cases, the results being reported in due time.

Instrumentation and Technique.—The production of fulguration sparks may be accomplished by means of very differently adjusted apparatus. Static electricity and the city current may be utilized, according to the case. The following list comprises the equipment to which de Keating-Hart gives preference:

(1) Electric source: city current, dynamos, or accumulators, etc.

(2) A table holding the rheostats, amperemeters, etc.

(3) A transformer coil with rapid interrupter, or transformer in the closed magnetic circuit (alternating current).

(4) A condenser furnished with a spark gap.

(5) Oudin's resonator.

(6) A bellows furnished, according to the case, with a foot-pedal, or with a tube of carbonic acid, or an electric bellows with disinfected air.

(7) Special electrodes of de Keating-Hart. (Fig. 45.)

(8) An operating table of wood or metal.*

A few details to be emphasized:

(1) The source of the current must be powerful.

(2) The amperage at the primary may vary enor-

Fig. 32.

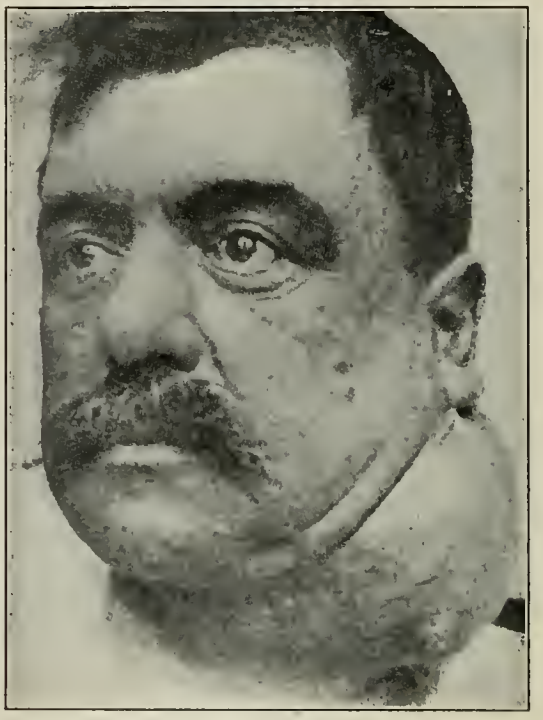

Fig. 33.

Cancer of the Cervical Region.—Case XVI.—This was a case of epithelioma of the left cervical region, the origin of which is uncertain, since it was not seen by de Keating-Hart until the patient had had two recurrences, and when it was impossible to determine the primary focus of the disease. The tumor was large, of rapid growth, fixed to the deep structures of the neck in the carotid region, and declared by several surgeons to be inoperable. Extensive operation. The location, appearance, and consistency of the tumor pointed to a diagnosis of sarcoma, but microscopical examination showed that the clinical diagnosis was incorrect, the tumor proving to be an epithelioma. Fulguration November 2, 1908, after removal of the entire macroscopic mass. During the fulguration of the surgical site it was found that a small metastasis situated in the posterior cervical region was left behind, but it was considered inadvisable to prolong the operation, since the patient was already in a condition of shock. This mass was fulgurated some months later. Perfect result. Complete cicatrization in a few weeks. Seemingly cured after three years. (See Figs. 32, 33, and 34.)

Fig. 34.

*The Bainbridge table (Fig. 46) was used for many of the fulguration operations during de Keating-Hart's visit. It is especially advantageous for this purpose, the metal of the table serving as the conductor. It is only necessary to expose a small area of the patient's naked body to the uncovered metal top of the table.

mously (from two to eight or ten amperes, according to the voltage of the current, and the manner in which it is utilized by the internal construction of the coil, etc.).

Fig. 35.

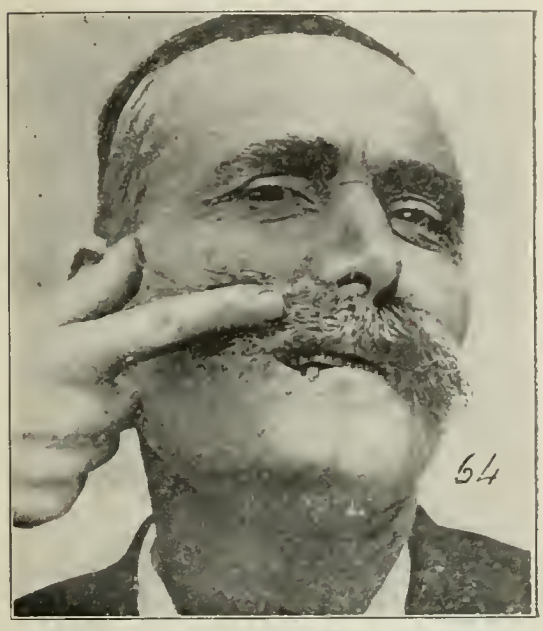

Fig. 36.

Case XVII.—Flat epithelioma of the angle of the mouth and lower lip, of recent beginning and rapid growth. Fulguration September 18, 1907. Removal limited to the macroscopic lesion alone, without removal of a margin of healthy tissue or of the glands, which were not perceptible to the touch. Cured for more than four years.

(3) The strength of the coil cannot be measured in terms of the length of the spark, as formerly, because of important modifications which have been introduced in the internal adjustment of the new apparatus. In the old models one was able to estimate a minimum of forty to forty-five centimeters of spark as the limit of the secondary. But the ensemble of the apparatus ought to be able to pro-

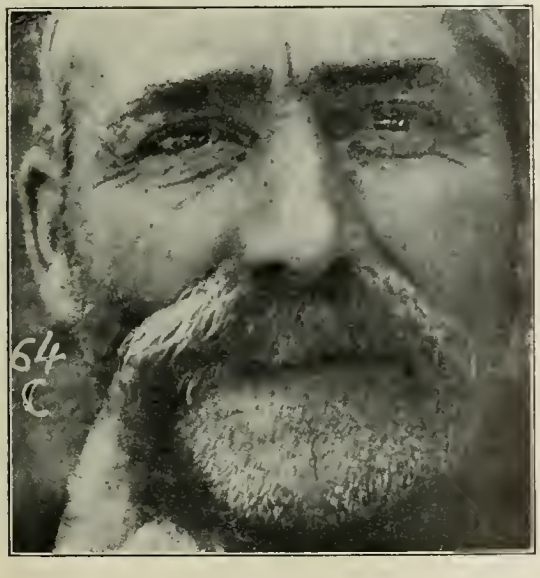

Fig. 37.

duce at the extremity of the solenoid, of the resonator, crackling white sparks of a minimum length of from seven to eight centimeters.

(4) The electrode, the special instrument for delivering the spark to the patient, is in the form of a sound. It is made of a smooth, metallic mandrel, or obturator, working snugly within an insulated tube of hard rubber. (Fig. 45.)

(5) The bellows produces during the operation a constant circulation within the hard rubber tube of a current of carbon dioxid, or, preferably, of air, the purpose of which is twofold: 1, to prevent a rise in temperature of the column of air within the electrode where the sparks are produced; 2, to remove the coagulable liquids which may obstruct the free end of the sound at points of contact of the latter with the operative field.

(6) This gaseous circulation first strikes the upper end of the sound and escapes at the tip. An electric contact is then established between the electric source and the metallic mandrel. The mandrel is then withdrawn from ten to twelve centimeters outside of its hard rubber casing, in such way that the point of the conductor is situated at an equal distance from the tip of the insulated sound. Consequently, in order to reach the fulgurated zone, the spark must pass through the non-conducting aerial column in the sound, which will permit the fulgurator to deliver sparks to those points only which it is intended to reach. For a large flat surface such an instrument may not be necessary. In all hollow places, or in all empty organs, a spark which is not thus surrounded by insulation spends itself upon the edges or upon certain points and cannot penetrate in its entire length to the bottom of the place in question.

(7) Even with this instrument perfected, as it is, one is not free from all error of technique, unless it be utilized according to certain principles and with precaution. The first precaution to take is the surveillance of the proper function of the apparatus. If the interior wall of the hard rubber tube is still moist after being sterilized, it may change completely the properties of the spark, and especially its

length, by prolonging the metal conductor through a conducting liquid as far as the inferior extremity of the instrument. Likewise, it may happen that in spite of the bellows, or, at least through its insufficiency, a coagulum may fill up the interior of the electrode, altering the force and the quantity of the current.

It would take too long to discuss here all the incidents which may take place in the course of fulguration, and, by changing the entire conditions, vitiate the results. From the foregoing it may be readily inferred that precision of technique is quite as essential in the application of the electrical current as it is in the preceding surgical operation.

Surgical Technique.—The first step of fulguration is purely surgical. This depends entirely upon

Fig. 38.

Fig. 39.

Case XVIII.—Epithelioma of the lower lip of the size of a small walnut, situated at the angle of the mouth. Enlargement of the submaxillary glands on the right side. Fulguration April 10, 1909. Removal of the tumor, incision of skin to right submaxillary region, ablation of the enlarged glands, and the degenerated submaxillary gland. "Sparking" of the entire wound. Cured for more than three years. (See Figs. 38 and 39.)

Fig. 40.

Fig. 41.

Case XIX.—Cancer of the left half of the tongue, with leucoplakia and bilateral cervical adenopathy. Removal in two sittings of the cervical and buccal lesions. The small glands on the right side were left in place (unfortunately). Fulguration March 21, 1909. Cured for nearly three years. (See Figs. 40 and 41.)

the exigencies of the case, and need not be given detailed consideration here. Fulguration is essentially a method of treatment for *operable* cancers. The more complete the removal of diseased tissue, the more certain, according to de Keating-Hart, is the freedom from recurrence. The possibility of complete cure and absolute prevention of recurrence is commensurate with the extent to which eradication may be carried. Where only partial removal of diseased tissue is possible the method of fulguration is palliative rather than curative. In these cases de Keating-Hart advocates another method—thermo-radiotherapy—which will be considered later.

Fig. 42.

Fig. 43.

Case XX.—Very large cancer of the cheek on the left side, developed primarily on the mucosa of the mouth from a spot of leukoplakia. The tumor invaded successively the superior maxilla, which it destroyed, and the skin of the cheek from the malar region to the ear and as far as the angle of the mouth. A part of the inferior maxilla was also involved. The tumor was treated for some time at Lyons with a high-frequency current, without operation. The tumor grew larger and larger. The patient was seen by Prof. Jaboulay in Lyons. Fulguration April 9, 1909, with the surgical assistance of Dr. Juge. Ablation of the macroscopic masses by means of the curette, the scissors, and the knife. The greater part of the left superior maxilla was seen to be completely cancerous. A sharp primary sparking was then done and repeated some days later upon some new nodules which had appeared at certain points of the wound. Has remained in perfect condition, without recurrence, for more than three years. (See Figs. 42, 43, and 44.)

Fig. 44—Actual condition (cicatrized). The tongue is seen at the bottom of the opening.

Electrical Technique.—The electrical technique is simple in its description and delicate in its application. The general rule laid down by de Keating-Hart is as follows: Spark for a long time, using powerful sparks of high frequency and high tension, applying them to the area from which every macroscopic trace of cancer has been removed. It is, then, *under* the cancer, and not *upon* it, that the electrical discharge is applied.

The spark should be white, producing the sensation of a violent shock, its mean length to be from ten to twelve centimeters. An important detail is to utilize the spark at its maximum length. The electrode should be kept in constant motion, and should be regularly passed over the surface being treated. The reason for this is twofold: (1) In order to avoid carbonization of the points at which the spark strikes the tissues; (2) in order to equalize the dosage, save at suspected points where one must work energetically.

The dosage, or the duration of the application of the spark upon a given point, it is impossible to establish in other than an empirical manner. It is not difficult to comprehend the reason for this, when one realizes that no two apparatus are exactly alike, and that in the same apparatus there may be great variations in the primary current, the distance of the sparkgap, and the conductibility of the air which surrounds it, all of which bear an influence, as does likewise the insulation of the patient. Under such conditions the electrical properties of the spark are subject to enormous variation. As a general rule, however, one may advise "ten minutes of fulguration for an area of ten square centimeters." This is near enough for ordinary purposes, in the majority of cases, and with the usual apparatus.

Another guide in the matter of duration is the change in the color of the tissues being fulgurated. All tisues take on a slightly darker tinge, not from destruction, but from the deposit of small blood clots produced at the surface through contact with the spark. This change of color varies with the tissue involved. While the muscles take on the tinge of smoked meat the bones become slightly yellow. In reality these appearances are apt to be deceptive, depending upon the manner in which the

sparking is carried out, and upon the thickness of the sanguinolent fluid through which it passes. As a rule, bones should not be fulgurated as long as the muscles, or the vessels as long as the tendons.

The two main points to be emphasized are: (1) Sufficient removal of diseased tissue; (2) powerful sparking of the underlying tissues.

The method should not be condemned unless these two essential features are practised. De Keating-Hart calls attention to the fact that most of the German authors, with the notable exception of

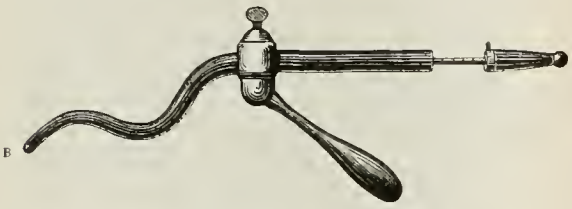

Fig. 45.—De Keating-Hart's Fulguration Electrode.

Czerny, have published only failures. This is accounted for by him by the fact that almost everywhere in Germany he has seen very defective electrodes employed. The apparatus in these instances permits of the use of a spark only about three centimeters long. Furthermore, this spark fails to affect the parts concerned when one is working at the bottom of a cavity.

Bad instrumentation and bad technique, combined with insufficient surgical intervention, are the chief causes of failure. In addition to these, an improper understanding of the indications for fulguration may lead to failure. Some tumors, because of their location (as in the intestine, uterus, brain, lung), escape the action of the spark. In such cases fulguration alone is not indicated, but a combination of fulguration and "thermo-radiotherapy," another method suggested by de Keating-Hart, of which we will speak presently.

Theoretical Basis of Fulguration.—During the visit of de Keating-Hart to this country full notes were taken of his lectures and demonstrations, in order that our test of his method might be in absolute accord with his views. In addition to this, he was asked to formulate for us a full exposition of the theory upon which he bases his claims concerning fulguration. What is said on the subject, therefore, is an abstract of his own statements. We wish to emphasize the fact that we are neither accepting nor rejecting his views, but that, as stated in the beginning, we are merely *examining* the evidence by clinical tests.

The premise upon which the de Keating-Hart fulguration method has been developed is that the *unipolar long spark of high frequency and high tension acts not upon the neoplasm, but upon the soil on which the neoplasm has developed.*

Three groups of facts are relied upon to establish the premise:

(1) That sparking, even when used with inadequate surgical operation, gives undeniable results, insufficient doubtless, but already very definite.

(2) That the tumor is in no way modified in its appearance or in its vitality, from which one may

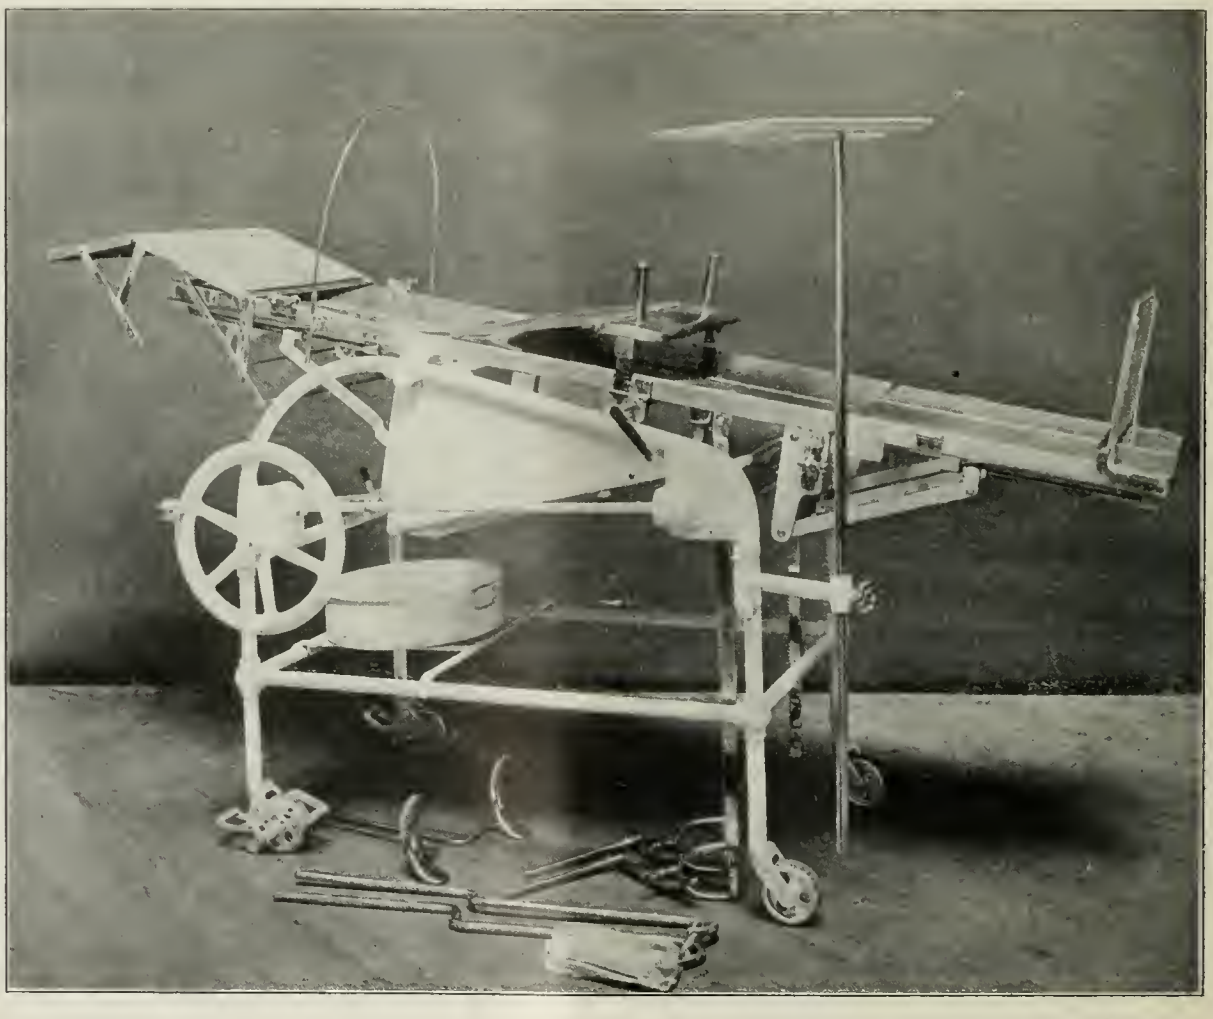

Fig. 46.—Bainbridge's operating table, the metal top of which serves as the direct connection with the electrical apparatus

reasonably conclude that it is not the tumor itself, but the condition of its nutrition—that is to say, the environment in which it develops—that is transformed.

(3) That laboratory experiments and clinical observations furnish plausible explanations of the foregoing.

The Action of the Current without Excision —"Sideration."

In his earlier attempts de Keating-Hart based his work upon a principle which he afterward found false, viz., he sought to produce, by means of the electric discharge, not an immediate and direct destruction of the tumor, as many thought, but what he called its *"sideration,"* by which he meant a sort of stunning of the cancer cell, in consequence of which the cell became partially devitalized and retrograded little by little, so that from a condition of anarchy there was a return to a condition of organized and orderly control.

By way of parenthesis, it may be emphasized here, that by "cancer cell" de Keating-Hart does not suggest a parasitic or microbic origin of cancer. He does not accept this theory of the etiology of the disease, but considers it rather the expression of the hypernutrition of abnormal cells. The object of his treatment, therefore, is to bring about a lessening of the nutrition of these abnormal, or cancer cells, and their death in consequence of this lowered nutrition.

His early results seemed to prove the correctness of this theory. The first case which he treated in this manner was one of cancer of the breast, "en cuirasse," in which division of the nerves had caused anesthesia of the cutaneous surface, permitting the application of violent sparkings many times a week to the affected area without anesthetizing the patient, and without giving rise to intolerable pain. Under this treatment the general condition improved very quickly. The tumor was adherent to the thorax, but was nevertheless quite superficial. It retrograded under one's eyes.

De Keating-Hart has since published a series of observations of the same kind, in which, despite the persistence of cancerous nodules in fulguration wounds, he obtained, after the application of his method, excellent and durable retrogressions, more or less complete, notwithstanding that previously the lesions were developing with rapidity, and that surgical intervention had aggravated rather than diminished them.

From these experiences he was convinced that the current, even when employed alone, or accompanied by inadequate surgical intervention, gives rise to remarkable results in cancer. He concluded, therefore, that the current is the active element in his method, but he could not at first determine upon what tissues the current acted, whether upon the unhealthy tissue, by destroying it, or upon the healthy tissue adjacent to the abnormal tissue, modifying the former. In time he reached the conclusion that the current caused the "sideration" of the abnormal tissue cells.

The Modification, by Sparking, of the Area Underlying the Tumor.—A previously determined fact helped to shake his faith in the hypothesis of the direct "sideration" of the cancer cell. He had seen cutaneous neoplastic nodules retrograde around a fulgurated region without themselves being touched by the discharge. A very simple experiment overthrew his first theory. He found that mice cancers, when fulgurated, removed, and reimplanted in healthy mice, developed afresh under conditions identical with those of grafts that had not been exposed to the spark. The neoplastic cell, not destroyed directly by the electric discharge, was in no way attacked in its vitality by the discharge.

It was necessary then to completely reject the "sideration" hypothesis, or that the high-tension current caused any notable modification of the neoplasm, whether physiological or histological. The evolution of the cancer, however, being indisputably diminished by the current, in his experience, he concluded that it could only be that the soil sustaining the lesion had been rendered less fit for its growth.

His observations, then, led de Keating-Hart to the theory that sparking modified the local trophism in such way that the tumor, being badly nourished, tended to retrograde. He announced this view at the Congress of Physiotherapy at Paris, in 1909, and afterward at the Congress for the Advancement of Science, at Lille, in the same year.

The observations and experiments which verified, in his opinion, the hypothesis thus modified, may best be given in de Keating-Hart's own words. We quote, therefore, directly from his statements, as published, and as forwarded to the author in a personal communication since the former's return to Paris:

"Facts and Experiments which Confirm the Hypothesis of an Action on the Subjacent Healthy Tissue.—The employment of the high frequency short spark (from one to four centimeters), that is to say, at a relatively low tension, produces the effect of cellular stimulation; it provokes a rapid cicatrization of wounds, and its remarkable action of the closure of torpid ulcers is too well known to require any insistence upon it.*

"On the other hand, the high-tension spark properly so-called, of a minimum length of seven centimeters, applied for a time sufficiently long in proportion to the surface fulgurated, *so far from activating cicatrization, retards it and transforms a given area into a torpid wound.* The wound fills up, but the surrounding healthy tissue contracts. The surface becomes hardly at all covered with epithelium. There is, in other words, a natural autoplasty, not cicatrization, and if the surrounding skin is but slightly elastic, the closing of the wound, far from being hastened, becomes extremely slow. By analogy, then, and considering the difficulty of the reformation of healthy epidermis after fulguration, I had to admit that the same trophic phenomenon that prevented such reformation retarded or suppressed the propagation (repullulation) of cancer *in situ.* New and very interesting experiments, previously unknown to me, have come to support, by histological examinations, my somewhat unsupported hypothesis. I refer to the researches of Professor Ghilarducci of Rome.

"On June 30, 1909, Ghilarducci presented to the Royal Academy of Medicine of Rome a communication in which he made known his researches on the 'biological and curative action of fulguration.' He says: 'the curative value of fulguration in malignant tumors is still the subject of much discussion. The method of Keating-Hart has both ardent partisans and strong opponents. I have treated by fulguration eleven almost inoperable cases: namely, three epitheliomas of the breast, two of the neck, one of the nose and the antrum of Highmore,

*Zimmern: "La Valeur Thérapeutique de la Fulguration," Paris, 1909.

one of the concha of the ear extending to the mastoid process, two carcinomas of the cervix uteri, and one carcinoma of the nasal septum. . . . The patients belonged to the services of Professors Allesandri, Ferreri, and Ferreti. The immediate results *have been good in those cases in which surgical excision could be practised in such a way as to comprise the macroscopic limits of the tumor.* I cannot express an opinion of the definite results, my experience being yet too recent.'

"But having observed the constancy of all the trophic reactions of the current published up to that time, and rightly admitting that all trophism is normally regulated by the nervous centers, he (Ghilarducci) has sought the causes of these phenomena in the modifications of the nerves and of the spinal cord consequent on fulguration. With this point in view he has made a series of experiments on rabbits. Exposing the animal's sciatic nerve, he subjected it to the current for from a second to half a minute. Then from day to day he examined macroscopically the histological results of these fulgurations. His work *in extenso* gives his observations in detail, which are too long to be recounted here. I shall content myself with a résumé of the principal conclusions, as follows:

"(1) The action of the current varies as the intensity and duration of the fulguration.

"(2) *It manifests itself at a considerable distance from the point fulgurated.* In his experiments, Ghilarducci has discovered in the *sacral and cervical segments of the cord even when not itself fulgurated, lesions corresponding to those that he had produced on the sciatic nerve subjected to the current, and that without modification of the intermediary nerve trunks or of the spinal ganglions,* as though the nerves transmitted the electric shock to the medullary cells without themselves suffering any consequences therefrom.

"(3) Finally, *the distant medullary lesions may vary from a simple chromatolytic reaction to a cellular necrosis,* according to the intensity and the duration of the application of the current to the sciatic.

"We know what profound troubles of nutrition may be brought about by the destruction of certain medullary segments, witness the retardation of growth that the limb of a child undergoes after an attack of anterior poliomyelitis. Is it not easily admissible that the modifications transmitted to the spinal cord by all the nerve terminals of a wound subjected to fulguration, should determine in it reactions that manifest themselves by a certain cellular destruction followed by a more or less complete repair? And would not that explain and justify, to use Ghilarducci's words, 'the analgesias and trophic troubles clinically displayed?'

"To sum up, I believe that I have shown that the reaction of the high-tension current employed in a *fulguration dose* in no way resembles that of other physical agents.*

"The retardation it causes to the epithelial covering of wounds, the retrogression that it provokes even in cancer nodules situated around the fulgurated zones, and, finally, the distant histological actions that it determines in the medullary centers corresponding to these zones, all suggest a seductive, even if yet incomplete, explanation of its success in the treatment of cancer. The ignorance in which we find ourselves regarding the exact pathogeny of these neoplasms, does not permit us to demand more from any theory. Certain experiments, however, now proceeding, will soon, I hope, permit me to support it with sufficiently forcible proofs. But the difficulty in the matter of dosage explains how it is that results can be so different with different experiments and cases."

34 Gramercy Park.

*"It is especially differentiated from 'diathermia' studied in Austria and Germany by von Berndt, Zeyneck, Preeps, and Nagelschmidt, and lately introduced into France under the name of 'electrocoagulation.' This is indeed only a thermic means of destruction, not a modifier of trophic centers. I do not discuss, but merely call attention to this method, so interesting from other viewpoints, which up to now has not given any result that has been seriously studied in cancer; and the work of the authors themselves of the method (Berndt, Nagelschmidt) have proved that the cancer cells *not destroyed by diathermia acquired on the contrary a heightened vitality.*"

RELATIONS OF CALCIUM TO PRETUBERCULOUS STATES, ARTERIOSCLEROSIS, AND INSANITY.

By CHAS. F. DISEN, M.D.,

MINNEAPOLIS, MINN.

FORMERLY PATHOLOGIST AND CHIEF OF THE TUBERCULOSIS DIVISION, CITY HOSPITAL, DEMONSTRATOR OF ANATOMY MINNESOTA STATE UNIVERSITY.

We are sometimes told that it is the doctor's business to disagree, but it may even happen that the doctor disagrees with himself and then a reconciliation becomes necessary.

While listening to a masterful and most inspiring lecture, delivered before the Hennepin County Medical Society by Dr. Tomlinson of St. Peter, who had been requested to tell about insanity, certain strings were set vibrating in my mind. We were told that insanity had a long prodrome and frequently was connected with a progressive arteriosclerosis that had begun at the time of puberty in offsprings from tuberculous ancestry.

Is there any relation between arteriosclerosis and pretuberculous states or tuberculosis? In practice we are interested in early arteriosclerosis, mainly of the gouty type, which again is found in the heavy meat-eater, the sedentary, or in the hard laboring man: he appears as the opposite of the pretuberculous, enjoys a good appetite for fat as well as for other foods, and usually gives the idea of a robust farm-bred or overfed person. The pretuberculous, on the other hand, with an innate disgust for fat, gives us the picture of a city-bred, delicate, or neuropathic individual. The physician at a glance recognizes each class. So, at least a *prima vista*, we have two distinct types among humanity, viz.: the antituberculous and the pretuberculous; denoting respectively the gouty and those descending from tuberculous ancestry or otherwise being predisposed to tuberculosis.

Arteriosclerosis is considered to consist primarily in a degeneration of the tunica media, effected by high tension. This, again, is caused by overwork and strain, bodily or mental, or by anything constricting the arterioles, as nitrogenous materials in excess of needs or with deficient excretion. Omitting the numerous other causes of early arteritis as tobacco and other vasoconstricting poisons, exogenous and endogenous, it seems that in the gouty type the difficulty is principally due to mechanical strains or nitrogenous excess. As we all know, arteriosclerosis does attack the tuberculous after some time, but the rationale of the pathogenesis is of a different nature. We

here have, besides denutrition, vasodilatation, giving diminished tension, and although agreed that arteriosclerosis depends on mechanical strain on the media, possibly interfering with the vasa vasorum, we would take exception in the case of tuberculosis. As arteriosclerosis first attacks the part of the media with no vasa vasorum, and this part as well as the intima is nourished by imbibition from the main blood stream, it must be plausible that in tuberculosis with vasodilatation the arteriosclerotic changes must be operated by direct imbibition of toxin, independently of either tension or interference with the vasa vasorum. Also in the pretuberculous arteriosclerosis develops under circumstances very different from those connected with the gouty type. Occurring more frequently in concealed parts of the anatomy, it usually evades the clinician, even the pathologist, and we must step down to the cell arrangement for elucidation. The all-important reticular nucleus that directs and controls the activity of the cytoplasm contains chromatin, plastin, nucleoproteins, calcium, iron, etc. The cytoplasmic reticulum fibers, continuous with those of the nucleus, are also composed of plastin and calcium. In the reticulum spaces we have (1) ordinary proteins, (2) nucleoproteins with phosphoric acid, (3) calcium combinations, and (4) proteins in combination with fatty acids, fat according to some, and phosphoric acid, thus including lecithins and the much discussed liposomes. I shall beg for the sake of convenience, also avoiding some hair-splitting contention, to designate all of the fourth class as lipoproteins. It may be convenient for an easy understanding to touch on the fat and calcium metabolism. The fatty elements attract calcium salts and further their suspension or solution by the high increase of carbonic oxide, as occurs during catabolism of lipoproteins. This enables the reticulum fibers and nucleus to assimilate calcium for the maintenance of the resisting power of the cell. Several researchers already agree that fatty derangements as myelin formations are the immediate forerunners of nuclear degeneration. Besides acting as a mechanical support the calcium content of the cell must also be reckoned as the important factor in inhibition of catabolism, and at times as a neutralizer of certain poisons. We must, as one of the important premises on which this article is based experimentally and chemically, admit that there exists a mutual attraction between fatty substances and phosphoric radicles on one side and calcium on the other. Intracellular deficiency of one determines intracellular deficiency of the other. Given a small calcium content of the cell, we shall expect the consequent increased catabolism to result in an undue loss of protein from the lipoproteins, and, at least occasionally, as in states of denutrition, to occur too quickly for the latter to be restored in due time by protein assimilation. Under such circumstances the setting free of the fatty materials from the lipoproteins may result in myelin formation, fatty degeneration, and, if the deranged fatty matters unite with calcium ions, we may get calcium soaps and calcareous degeneration. This may be the modus operandi in the pretuberculous of acquiring arteriosclerosis. Occurring as a phase of denutrition it must be fundamentally different from arteriosclerosis in the gouty who as often suffer from hypernutrition and naturally require treatment of an opposite nature in spite of similarity in microscopic appearance. As for inhibition becoming diminished by a loss of calcium, we have evidence in the tetany following removal of the parathyroids, since this event has been found to be accompanied by a loss of that element from the cerebral cells. Even, if, as some may aver, the operation results in an intravascular accumulation of monovalent cations or ammonium combinations that may antagonize calcium, it is yet the calcium that inhibits. Loss of calcium by lactation is said to have caused spasmodic conditions. Again, in spasmophilia, calcium has proved beneficial. In this condition an interesting clinical proof is evinced of the interrelation between fatty matter, phosphorus, and calcium. For if in such a patient an increase of extracellular fat be allowed the spasmophilic condition becomes accentuated, because the extracellular fat takes up some calcium that otherwise would have entered lime-wanting cells. Give less fat, more lime, and the patient improves. If instead of calcium we give phosphorus, relief similarly occurs, as phosphorus enhances resorption of calcium. In the antiperistaltic action of calcium we have another proof of inhibition, and, with such several evidences at hand the catabolism-inhibiting virtue of calcium can hardly be doubted.

What do we know about deficiency of calcium as determining a pretuberculous state or predisposition to tuberculosis? Pregnancy and lactation are said to favor tuberculosis, and we cannot doubt that much of calcium is being lost under both circumstances. Workers in lime-kilns are reported immune. Diseases of the heart afford immunity by loading the system with carbonic oxide which, we know, favors calcium anabolism. The immunity of the gouty may be explained by his abundant assimilation of calcium, since his appetite for meat serves well to maintain the intracellular lime-attracting lipoproteins, while a perambulation of the abundant acid radicles, obligated by a high nitrogenous intake, necessarily enhances resorption of calcium. Again, considering that the poison of the tubercle bacillus is a nucleic acid, a sufficiency of intracellular calcium would afford a mode of neutralization. Lastly, it may not be an absurd idea that the mechanical or biochemical cell-strength, insured by calcium, would of itself offer protection against the tubercle bacillus. Anyone can verify that the leucocytes of the pretuberculous are very frail as compared with those of the gouty. If a pretuberculous state be inherited, we may consider that the chromosomes of the nucleus of the ovum as well as the reticulum fibers, resulting from the pulling apart of the former during the anaphase to form the daughter cells, may contain too little calcium to begin with.* The resulting delicate framework would expectedly exist in all of the cells of the embryo, and we get our pretuberculous individual with poor affinity and inborn disgust for fat.

Having already established how the pretuberculous can acquire arteriosclerosis, where do we expect it to occur? As Dr. Tomlinson has said, the brain as the last organ, and more especially the arrangements of inhibition, as underlying the very last and highest functions evolved, would be the

*An inherited defective adrenal system, involving the parathyroids, would be a competing factor.

favorable seat of arteriosclerotic changes in the pretuberculous; and following the spirit of this paper, such indeed would be inferable. For if we grant deficiency of calcium, a consequent poor affinity for fat, and consider that the brain needs much phosphorized fat with proportionately more calcium, then if it does not get a sufficiency we shall in the brain pre-eminently obtain those conditions already given as favorable to the development of arteriosclerosis. For a deficiency in fat-content again implies less resorption of lime, diminished inhibition, and increased catabolism with occasional setting loose of fatty matter and degeneration in consequence. As the grey matter is known to need more calcium than the rest of the brain, degeneration of the neurones may supervene on the same principle. As for the progressiveness of the arteriosclerosis we again must seek explanation on the inhibition basis. Suppose we visit the association spheres, the seat of unconscious and associative memory, and ask ourselves what defective inhibition in this territory would promise. We should have a diminished impediment to mental impressions, a rapid, more or less direct transmission of thought-elements from cell to cell, not stopping or switching off for deliberation. Or we may have the impulses overflowing to sociologically foreign association groups. Thus we get magnification or distortion of impressions, pleasant or unpleasant, and although the brilliant thinker who soon wears himself out, and the deteriorating genius with his grotesque associations may thus be evolved as likely as the criminal, yet, in most instances, the person suffers at bottom from a dominant, naturally resulting lack or difficulty of mental control that makes the highly self-conscious even shun society. We simply in all this have different phases of a frequently harassing heightened catabolism: If we now imagine effects of the constant strain involved in the adjusting of an unsteady mind to the requirements of advancing civilization, not forgetting an eventual magnification of the worries and axieties to which most people become subjected when they must provide for themselves, then it might be no myth that a progressive arteriosclerosis would be favored after the time of puberty. A sudden or severe mentral strain on such a subject may precipitate insanity if other psychobiological antecedents allow. The fact that the grey matter needs more calcium than the white speaks for the views adduced.

While writing these very lines a tangible illustration was afforded by a case just brought to my office, viz., a seventeen-year-old girl of tuberculous family. Her father complained that she would talk incessantly during the time of menstruation, indulging so much at her last period that exhaustion resulted and medical advice was deemed necessary. As admittedly large quantities of calcium are lost during menstruation, the logic of the case is self-evident if we accept the theories promulgated, and a clue to management is directly at hand.

As for treatment, while the gouty needs less of meat and nuclear material, the pretuberculous certainly needs a good share of both in order to maintain lipoproteins and to furnish acid radicles. By a short-cut reasoning from this paper we should simply shovel into him lime, but it probably as often devolves upon us to make him assimilate that which he already may be receiving in his food. For such purpose I recommend, besides underdone beef, phosphoric acid. Probably HCl in milk, as recommended by Dr. Russell for the tuberculous, but in smaller doses, may do well. If the urine exhibits normal or high acidity I give calcium. Country sojourn, as affording fewer irritating impulses or any life or work giving little worry and anxiety is highly commendable since a sense of security is the great keynote acting as a psychic damper on mental catabolism. I believe that insanity can thus be frequently prevented.

ADVANTAGES AND DISADVANTAGES OF PLASTER-OF-PARIS AS A FIXATIVE APPARATUS.

By ROLAND HAMMOND, M.D.,

PROVIDENCE, R. I.

For many years plaster-of-Paris has been a *sine qua non* in orthopedic and surgical work. Its firmness, durability, and the ease with which it can be applied, have combined to render it almost indispensable in the treatment of tuberculosis of the various joints, in scoliosis, in fractures of the lower extremity, and after operations for the correction of congenital dislocation of the hip, bow legs, knock knees and club feet. The cumulative experience of the past points to a long record of successful treatment of these deformities, but of late years there has been a tendency with many surgeons to substitute surgical operations and mechanical appliances for the time-honored plaster-of-Paris.

Feiss[1] has called attention to the advantages of braces over plaster jackets in Pott's disease. He claims that the jacket does not correct the deformity nor even hold what correction has been gained; that it does not even fix the spine. By reason of the expansion of the plaster, and the matting down of the padding, the jacket soon becomes loose and allows so much motion that the requisite fixation is not obtained. Furthermore the jacket cannot be removed for a long period of time, and is therefore not cleanly. Respiration is impeded—an important factor in the growing child. The function of the cutaneous nerves is interfered with, and circulation is disturbed. Desquamation does not take place normally, and when the plaster is removed, a rough, scaly skin is observed. We have recently been treating cases of tuberculosis of the spine on the curved Bradford frame, and are pleased to observe that not only is the kyphos prevented from increasing in size, but the child's condition is much better than when wearing apparatus. The disadvantages attending the use of braces and plaster-of-Paris are avoided.

In treating fractures of the leg with plaster-of-Paris it is impossible to get at the limb and apply massage and early passive motions to the joints, which is such an important part of the modern treatment of most fractures. This can be accomplished, in a way, by bivalving the plaster and removing the upper shell. The massage and passive motions can be used, and the upper shell reapplied and held in place by adhesive plaster straps and bandages. But the plaster is still open to the objections of uncleanliness, interference with circulation and nerve supply, and atrophy of bone and soft parts. We have given it up in fractures of the upper extremity be-

cause splints and lighter dressings serve the purpose better.

In fixed rotary lateral curvature of the spine, on the other hand, no apparatus seems to give such good results, in the hands of most orthopedic surgeons as plaster-of-Paris. A few men, among whom are Adams[2] and Feiss, have the mechanical ability to use braces with success, but the majority of surgeons obtain their best results with plaster jackets.

Plaster has been the accepted treatment in club foot for many years. Of late, certain operations have been devised which are expected to hold the foot in correction without plaster or brace. More experience with these operations is necessary before passing judgment, but the use of plaster following manipulations and tenotomies will no doubt occupy an important place in the treatment of this deformity for many years to come.

In the treatment of congenital dislocation of the hip, a few orthopedic surgeons have used successfully a brace instead of plaster for holding the femur in its new position after the operation. Most surgeons have found plaster just as effective and more convenient to employ.

The recent work of some Italian and German surgeons seems to indicate that in using plaster-of-Paris we are dealing with a two-edged weapon. Anzoletti[3] and Roepke,[4] and later Hohmeier,[5] have shown that by applying plaster in the rhachitic deformities of the legs, a softening of the bones takes place, so that at the end of four to six weeks, the leg can be easily moulded into a corrected position. This is accomplished without giving an anesthetic and without performing an operation. It is rather startling to be made to realize that a plaster bandage, which we have applied in the firm belief that it aided in producing solid union and calcification, should really cause the bones to soften and the lime salts to disappear.

When we consider the evidence, however, the truth of the assertion is convincing. It is well known that in taking a Röntgen plate of a limb which has been in plaster for several weeks, the bone shows much increase in radiability throughout its textures, due to disappearance of lime salts. This occurs in a healthy as well as a diseased or fractured bone. It has been observed for many years in our hospital wards that if children were allowed to walk after the legs had been in plaster for a few weeks, the bones bent, showing that softening had occurred.

At the Rhode Island Hospital we have recently treated cases of bowlegs, especially those of the anterior type or saber deformity, by the use of plaster to obtain softening of the bones. At first we followed Anzoletti's method, and applied the plaster before attempting to correct the deformity. More recently we have given ether first, and corrected the deformity manually as much as possible. The correction gained at the first sitting may be only slight, but by changing the plaster at intervals of two weeks, the ultimate correction is obtained just as well and in a shorter space of time. This method is of course more applicable in young children with pliable bones. Osteomy and osteoclasis are preferable in older children and in cases where the bone is sclerotic.

INDICANURIA AND THE PROTEINS.

By JOHN C. WARBRICK, M.D.,

CHICAGO, ILL.

If indican is present in the urine in health and if normally there is always a little present without causing any serious trouble it might be supposed that on a certain diet, especially one consisting mostly of protein articles of food, it would increase a good deal more. This is particularly the case if this form of diet is followed out for a number of consecutive days. In order to determine the relation of indicanuria to a diet consisting principally of proteins taken regularly for a number of consecutive days, and mostly of the same articles of food, a good many examinations of the urine were carefully made after each meal. Sometimes three examinations were made after a single meal, but at intervals, to find if there was any diminution or increase in the amount of indican. Then the amount of chlorides, phosphates and sulphates, and also the degree of indican present, were all noted from time to time and the results were compared. The protein diet followed was mostly one of eggs, but some meat was also taken, together with other articles. For instance, at one meal three light boiled eggs were taken along with three pieces of toast, coffee and a glass of water. Then the urine was examined and records were made in each instance of the amount of indican, chlorides, phosphates, and sulphates and also the color of the urine and its specific gravity. Then again the first day it was examined after a few hours' interval to see what changes, if any, had occurred without the taking of any more liquid or solid food. Once more on the same day it was examined to find out if there were any changes from the previous examinations. After the first meal in the morning the amount of indican was above normal as indicated by the figure 6 according to the method used by A. Robin. This consists of Obermeier's reagent, which is chemically pure hydrochloric acid 1000 cubic centimeters, ferric chloride 2 grams, a 25 per cent. solution of lead acetate and a solution of potassium chlorate, 34.6 grams to water 1000 cubic centimeters; also 2 cubic centimeters of chloroform. To 10 cubic centimeters of urine add 1 cubic centimeter of lead solution and filter. Put 5 cubic centimeters of the filtrate in the test-tube and add 5 cubic centimeters of Obermeier's reagent; then add 2 cubic centimeters of chloroform and shake the mixture a number of times. The chloroform will be colored a light or a dark blue if indican is present. Add drop by drop some of the potassium chlorate solution until the blue color disappears, shaking the mixture all the time. Some may find this method rather tedious to do every time in estimating the amount of indican, but it is a reliable and a correct method to use and need not take any longer than a minute to perform. When the index figure of indican was at 6 at the first examination the specific gravity of the urine was not high nor was the amount of chlorides present very great. At the next examination a few hours later in the same day the amount of indican was the same as at the first test, as indicated by the figure 6, while the specific gravity was low at 1016 and the chlorides were not very high, being much the same, 25-387.

At the next examination about two hours later the same day the amount of indican diminished to the figure 4, while the amount of chlorides was much the same. Still later the same day something was taken to eat and the urine was examined for indican and was found to be the same as indicated by 4. This was all in the same day. The next day there was a rise in the specific gravity to 1026 while the amount of chlorides increased to 45-697, but the amount of indican was the same, at the index 4. After breakfast on much the same diet the specific gravity increased to 1028, while the chlorides remained the same at the high figure of 45-697.5. Also the amount of indican was the same at 4 and a dark blue. This was at 8 A. M. At 9 A. M. on the same day the specific gravity fell to 1022, the chlorides diminished to 35-542, while the amount of indican was reduced a point to the figure 3, being pale blue. At 10 A. M. the specific gravity was the same, while the amount of chlorides diminished to 30-465 and the amount of indican to 2. At 11.30 nearly sixty ounces of water were taken during the course of a short time, about half an hour, or less. At 12 P. M. an examination of the urine was made when the specific gravity was found to be reduced a good deal to 1010, but the amount of indican remained the same at the figure 2, while the chlorides increased to the amount of 35-542. At 1 P. M. a heavier meal was taken, including fish and meat, while at 2 P. M. the specific gravity of the urine was reduced to the low figure of 1004. The chlorides were also reduced to 20-310, while not a trace of indican in the minutest amount could be found. When the amount of indican in the urine was at 6 at the beginning it was at the end of twenty-four hours completely removed from the system. The amount of indican seemed to gradually diminish at each examination made and was present every time until the last instance of the ten examinations.

The amount of chlorides gradually increased from 20-310 to the high figure of 45-697.5, found at two examinations; then from this time it gradually decreased until the last result showed it to be at the figure of the first examination, 20-310.

From a gradual increase in the amount of chlorides until the high tide was reached at 45-697.5 we might naturally look for an increase in the amount of indican also and much more so when protein food was the chief article of diet. Especially was this to be expected at the last meal, including coffee, from which combination we should expect to find some increase at least in the indican from the last analysis of the urine. However, this was not the case, for with an increase in the amount of chlorides there was a steady decrease in the amount of indican under these circumstances. The amount of sulphates being stationary at point 1 during three examinations increased to 3 and remained at this figure for only two examinations. The amount of sulphates did not gradually increase with the amount of chlorides as it might be expected to do until the high chloride tide of 45-697 was reached, when the sulphates increased to 3. Now, in spite of the fact that the chlorides were increased and that the sulphates increased also, although not for any length of time, there was no increase in the amount of indican at all, but otherwise a decrease. The phosphates, as will be seen, remained much the same from the beginning to the end. They were at 3 during the first report and only increased once a single point to 1 during all the remaining examinations. Where the amount of chlorides was high the specific gravity of the urine increased and also the color which deepened some.

From all that has been written about the presence of indican in the urine and the causes that tend to produce its formation, it might be supposed that on a certain diet, especially one consisting chiefly of proteins, an increase of indican would occur, but under these circumstances the increase did not take place. On the other hand, the indican disappeared in a short time, without much trouble and also without any medication whatever. It might be supposed, and reasonably so, that indican may form more readily in the urine of some persons than in that of others, while it may be more difficult to remove it from the system of some individuals than from that of others.

April 7—2 P. M., dinner, 3 soft boiled eggs, 3 pieces toast, 2 cups coffee and a glass of water. Urine examination: Specific gravity, 1016; yellow; indican, 6; chlorides, 20; phosphorus, 3; sulphur, 1. 7 P. M., specific gravity, 1016; yellow; indican, 6; chlorides, 25; phosphorus, 1; sulphur, 1. 9 p. m., specific gravity, 1016; light yellow; indican, 4; chlorides, 25; phosphorus, 1; sulphur, 1. 11 P. M., 2 cups of coffee, corned beef, bread. Urine examination, specific gravity, 1016; light yellow; indican, 4.

April 8—7 A. M., specific gravity, 1026; yellow; indican, 4; chlorides, 45; phosphorus, 1; sulphur, 3. 8 A. M., 3 boiled eggs, 3 pieces of toast, 2 cups of coffee. Urine, specific gravity, 1028; yellow red; indican, 4, dark blue; chlorides, 45; phosphorus, 2; sulphur, 3. 9 A. M., specific gravity, 1022; reddish yellow; indican, 3, pale blue; chlorides, 35; phosphorus 1; sulphur, 1. 10 A. M., specific gravity, 1022; reddish yellow; indican, 2; chlorides, 30; phosphorus, 1; sulphur, 1. 11.30 P. M., water, 60 ounces. 12 noon, urine, specific gravity, 1010; bright yellow; indican, 2; chlorides, 35; phosphorus, 1; sulphur, 1. 1 P. M., dinner, soup, fish, meat, bread, 2 cups of coffee and potatoes. 2 P. M., urine, specific gravity, 1004; pale yellow; indican, none; chlorides, 20; phosphorus, 1; sulphur, 1.

INNOCENT COLON BACILLI IN URINES.*

By ANTHONY BASSLER, M. D.,

NEW YORK.

In the ardent search for the cardinal signs of a disease, and in the still present tendency in medicine of binding ourselves by an obsolescent system of classification and by an inadequate terminology, difficulty is encountered in seeing things of worth in other fields than our own, even when these pertain to conditions in which we are the most interested. The time-honored classifications, based upon clinical observation aided by morbid anatomy, are breaking ground for those which have their foundations in bacteriology and ampler pathology. This broadening and unifying tendency will not make for the destruction of the specialties, as some believe, but for better specialists, and it is possible that a new type of medical men known as diagnostitians will be necessary to help them.

Of late years the medical literature of the country has so thoroughly presented the importance of *B. coli communis* in connection with inflammatory and infectious conditions in the urinary tract, that one is inclined to assume that a urine containing many

*Read before the New York Academy of Medicine, May 15, 1912.

of them has a stern pathological importance of genitourinary interest. That such a urine commonly does have this pathological importance there is no question, but to show that it does not always have it is the purpose of this paper. It is stated that there are three modes of infection by which bacteria can gain the urinary canal: (1) ascending infection by the path of the urethra; (2) descending or hematogenous infection where the organisms are conveyed from a primary focus to the urinary tract and excreted by the kidney; and (3) transparietal infection through the lymphatics from the intestine to the urinary tract and bladder mostly. Since *Bacillus coli communis* is a common denizen of the intestinal tract of all mammals, it is probable that most of the coli infections of the urinray tract take place in the hematogenous way in the kidney cases and the transparietal in the cystitis. Whether a lesion in the intestine is necessary for its liberation from the gut I do not know, but there is substance for this belief in the pyelitis, septic nephritis, or cystitis occurring in the convalescence of typhoid, dysentery, or acute diarrhea; in the transitory coli hematuria that follows operations for appendicitis and other surgery upon the intestines, even to hemorrhoids. Granted that this is so, there is also good reason for the belief that bacteria under certain unknown conditions can pass through the walls of the gut and gain the body in that way. This has been proven and that it is more common than ordinarily believed the following would seem to suggest.

The largest proportion of cases that I have to deal with are those of states of chronic excessive putrefaction in the intestines. To make these diagnoses properly, detail work in the examination of the feces and urine is essential. Several months ago while examining a urine sediment with the low power and split illumination (which gives a fair degree of dark field effect) I noticed that in certain areas of the field particles on the slide were in motion. At first I thought this to be due to coursing of small amounts of urine carrying particles with them disturbing others on their way. Further observation proved that all of the specimen on the slide was stationary and that this movement was localized in certain areas. At one place I noticed a small urinary cell to be raised on one side edge up, and then drop back, perhaps being carried a short distance before it rested on the flat again. In another area amorphous matter was being pushed about in a fibrillary movement. Evidently there were present bacteria of an actively motile form doing this which the low power did not magnify enough to discern. The medium power showed the presence of many active bacilli, which were more plainly seen with the high power lens and dark field substage and arc light. With the latter instrument and an amplification of about 1,200 there were seen in this urine from four to twenty of these organisms in each field, which grown in culture and differential staining proved to be organisms of the *B. coli* class. This urine was from a female patient, so I thought that perhaps it had become infected as it was being voided from the urethra by contamination from the close-by anus, or from a chamber in which the twenty-four-hour collection of urine was being saved and in which feces had been deposited at some time before. A few days following this I examined a specimen from a male patient who collected his urine in a sterile jar and noticed the same phenomena in the sedimentary fields. Here we could exclude a close anatomical connection between the urethra and the anus, so evidently the organisms (which proved to be *B. coli* again) must have been voided in the urine. On examination of the histories, of the stool findings, and other points in the urine to confirm them, I noted that both of these urines were from cases in which a high *B. coli* content in the intestine was a definite clinical condition —that is, cases of chronic excessive intestinal putrefaction due to the *B. coli communis* as the predominant organism.

My interest being awakened in the matter, I observed sediments of each urine since then, and when I noted motile bacteria in them (providing the urine was from a male patient and had not come in contact with a bedroom chamber), I inoculated sugar tubes with a small portion of the sediment to test for *B. coli*. Altogether since then 191 fresh urines have been examined for the first time, and in these the colon bacilli in large numbers have been encountered eight times, and in smaller amounts ten times; thus the colon bacilli were present in over 9 per cent. of all urines from persons having no genitourinary symptoms. As most of these were cases of intestinal putrefaction in which one might expect this phenomenon, it is significant to observe that seven of them were not. It seems, therefore, that *B. coli* in considerable amount in urines is not uncommon in the nonputrefaction cases, although somewhat more commonly met with in them. None of these patients had any symptoms suggestive of kidney or bladder disturbance, and there were no pus cells in the urines indicating inflammation or concomitants of infection. What makes me feel that perhaps some catarrhal condition of the bladder existed in most of them was the rather high content of mucus found, but I have observed just as high contents of mucus in urines in which no infecting agents could be ascribed as probable causes, and not all of my cases showed this. It is reported that in mild *B. coli* infections of the bladder, little change can be noted in the appearance of the interior of the organ, of which the most notable lesions are congestion and swelling around the neck of the bladder and in the area of the trigone, and a possible general anemia of mucous membrane with here and there areas of congestion. But in these cases certain urinary symptoms are present to warrant the employment of a cystoscope, whereas in mine these were absent and thus its use was unnecessary and even not to be advised. All of these urines were more or less foggy looking, suggesting a bacteriuria, and very highly acid —no doubt, from products of these bacilli, which are energetic acid-makers.

We know that in systemic states supplying them, the pyogenic organisms, notably the coccal forms, and the tubercle, typhoid, and colon bacilli are found in urines. In a general way, however, it is understood that urines of normal persons are practically sterile of pathogenic organisms. The colon bacilli are not as pathogenic as the other forms mentioned, but when present in large numbers in the body outside of the intestinal tract they are considered pathogenic. While this is very possible in a general way, I feel that in so far as the bladder is concerned it is not always so, and it seems that pus must be present with them to consider it as such. There are apparently normal individuals whose bladders are incubators, and whose urines are the media for the proliferation of *B. coli* which does not seem to do any harm to them, and the presence

of which need not concern us very much. In the constituents of normal urines there are carbon, nitrogen, hydrogen, and salts in solution for their growth and proliferation, and, not requiring oxygen, they grow, utilizing these products to sustain themselves. While urine is far from a perfect culture medium to grow *B. coli* in, this organism can utilize it if needs be and get along well with it when there is nothing else to have and the urine is within the body. Experiments that I have made on the average normal urine inoculated with *B. coli* is that the microorganism cannot proliferate to any considerable degree. But it does to some extent, and is not destroyed by any normal urine I have yet experimented with. It is a fact that there are not a few apparently normal individuals whose daily output of urine contains not much fewer coli bacilli than their feces do, and that many more have them in lesser amounts. It is probable that the gases that these organisms must generate go into solution in the urine in the bladder. This can be further proven by placing such coli urines in fermentation tubes, when, after standing for days, although the coli bacilli are actively proliferating in them, very little gas formation is present.

126 East Sixtieth Street.

THE DIFFERENTIAL DIAGNOSIS OF PULMONARY TUBERCULOSIS:

A STUDY BASED UPON 519 NON-TUBERCULOUS CASES ADMITTED TO GOUVERNEUR TUBERCULOSIS CLINIC FROM NOVEMBER 1, 1903, TO NOVEMBER, 1910.*

By I. P. STARR, M. D.,

NEW YORK

ASSISTANT ATTENDING PHYSICIAN GOUVERNEUR TUBERCULOSIS CLINIC.

A study of differential diagnosis is of peculiar importance in pulmonary tuberculosis because of the acknowledged difficulty in recognizing cases in their incipiency, and the great importance both to patient and to the community of this early recognition.

It is generally admitted that the physical signs of an incipient case may be so slight as to escape even the trained observer, and on the other hand the symptoms with which such a patient presents himself may simulate a variety of other diseases. In the great number of cases presenting themselves at the tuberculosis clinic of a city hospital, such as Gouverneur, a certain number of puzzling incipient cases are seen, and a large percentage of patients wrongly diagnosticated as tuberculous and suffering from other conditions.

A study of these non-tuberculous cases seems to us of interest and importance for the following reasons: (1) These cases were referred to our clinic on the suspicion, or with a positive diagnosis, of consumption. They may therefore be considered as fairly representing the types of cases usually confused with pulmonary tuberculosis and most often mistaken for it. (2) In the majority of these cases, the history and symptoms correspond so closely with those of the positive cases that a comparison of the two groups is not without value. (3) So many of these cases were directly exposed to tuberculosis that they demanded careful and prolonged observation on that account if for no other. Finally, the ultimate decision recorded affords the best practical study of differential diagnosis at our disposal.

Out of the total of 2,151 cases included in this review, 519 were grouped as non-tuberculous.* Doubtless, in some of these, our decision was at fault or based upon insufficient observation; but all cases discharged at any time from the clinic as non-tuberculous, and later readmitted with positive signs (either acquired in the interval or originally overlooked), are excluded from this group.†

Of these 519 non-tuberculous cases there were 276 males and 243 females. The ages represent all decades, the greatest number, as with the positive cases, falling between twenty and forty years. Thus, there were 38 under ten years; 116 between ten and twenty years; 132 between twenty and thirty years; 120 between thirty and forty years; 81 between forty and fifty; 19 between fifty and sixty, and 13 over sixty years of age.

The family history in these cases is as frequently positive or suspicious as in the tuberculous cases, 99 giving a history of tuberculosis in one or both parents, 74 with a suspicious family history, and 346 without any history of tuberculosis. That is, there were 19.2 per cent. with positive histories; 14.2 per cent. with suspicious histories, and 66.6 per cent. with negative histories, as compared with 22.9 per cent. positive, 2 per cent. suspicious, and 73.5 per cent. negative histories in the tuberculous cases.

Naturally, the commonest symptom in all these cases was cough, 224 of this group coming to us with that complaint alone. Other suspicious symptoms—as hemoptysis, fever, loss of weight or strength—were also presented, as the following summary of the complaints on admission will show:

Complaints on Admission	No. of Patients	Percentage in Non-Tuberculous Cases	Corresponding Percentage in Tuberculous Cases
Cough	224	43.2	47.1
Cough and pain in chest	42	8.1	....
Cough and dyspnea	24	4.6	....
Cough and hemoptysis	17	3.2	3.4
Pain in the chest	66	12.7	9.9
Hemoptysis	16	3.08	2.5
Weakness	20	3.9	5.9
Chills, fever and sweats	6	1.15	1.0
Loss of weight	3	0.57	0.4
Digestive disturbances	20	3.9	4.1
Symptoms referable to the throat	15	2.8	4.7

Twenty-seven presented no symptoms whatever (5.2 per cent.); and in 39 cases (7.1 per cent.) the symptoms were not suggestive of tuberculosis.

The duration of these symptoms previous to admission to the clinic was as follows:

Duration of Symptoms	Number	Percentage	Corresponding Percentage in Tuberculous Cases
Under one month	73	14.0	7.3
1 to 3 months	49	9.4	11.9
3 to 6 months	74	14.2	17.0
6 to 12 months	56	10.7	20.2
1 to 2 years	63	12.1	15.5
2 to 3 years	58	11.1	8.2
3 to 5 years	45	8.7	7.7
Over 5 years	55	10.5	6.9
Not stated	46	8.8	1.1

The comparison of percentages shows a relatively higher average for the non-tuberculous cases at the extremes of the table, while the most frequent duration recorded for the positive cases was between six months and one year.

The number of these cases giving a history of

*Submitted at Staff Meeting in February, 1911.

*This is exclusive of the children of tuberculous patients discussed in a separate section.

†There were, in all, only 11 such cases, and they were studied under the section on Special Cases.

direct exposure to tuberculosis was seventy-seven, *i.e.* 14.8 per cent., as compared with 21.1 per cent. of those with a history of exposure in the positive cases. That is to say, they came, in part at least, from that portion of the community in which tuberculosis is to be expected and sought, *i.e.* among those living with the tuberculous.

The final diagnosis reached in these cases is, after all, the point of great interest, medically, in our review of the non-tuberculous charts, since it summarizes the commonest errors which may be made in favor of tuberculosis, as well as grouping together the diseases most often confused with it. In a number of our non-tuberculous cases, no diagnosis was possible, on the data charted, except for the single term "negative," for at the time of discharge all symptoms had disappeared and in these cases there were no significant physical signs. Doubtless many of them came in with tracheitis, subacute bronchitis, or nose and throat conditions giving rise to cough, but we have no positive evidence in support of this supposition. There were 284 such cases dismissed as negative. Of the remaining 235 there were 53 cases of chronic bronchitis and emphysema; 48 cases of simple bronchitis; 49 cases of chronic endocarditis; nasal obstruction (adenoids and hypertrophied tonsils), 15; anemia, 6; leucemia, 2; lobar pneumonia, 4; asthma (bronchial and cardiac), 6; tuberculous osteomyelitis (with pulmonary involvement), 4; pleurisy (non-tuberculous), 5; acute laryngitis, 2; cervical rib, 2, and 55 miscellaneous diagnoses, including such diverse conditions as cirrhosis of the liver and exophthalmic goiter. Six charts bore the diagnosis of "healed lesion," the physical signs being suggestive only of the old tuberculous process entirely inactive.

The difficulties involved in the differential diagnosis of such cases, presenting histories and symptoms so similar to those of our positive charts, are well illustrated in this list of the conditions which were suspected of, or mistaken for, pulmonary tuberculosis. Any illness accompanied by cough, loss of weight or color, pain in the chest or dyspnea, weakness and rapid pulse may be suspected of tuberculous infection, and such a suspicion is often confirmed or refuted only after repeated examinations and a considerable period of observation. From our figures it would seem that the commonest condition to be mistaken for pulmonary tuberculosis is chronic bronchitis associated with emphysema. Our experience, however, leads us to believe that the association of these two conditions is much more frequent than its recognition. Thus, while there were 53 cases of chronic bronchitis and emphysema discharged as not tuberculous, there were 24 cases of pulmonary tuberculosis complicated by chronic bronchitis and emphysema, separately or in combination. The difficulty in excluding tuberculosis in these cases is due to the variety rather than the deficiency of physical signs. In a chest full of râles and presenting the emphysematous type of resonance and breath sounds it is sometimes difficult or impossible either to detect or to exclude tuberculosis, however suspicious the symptoms or history. Often only a positive sputum after a number of negative examinations decides the question. Contrary to the older teaching, the two conditions seem to occur together with comparative frequency.

That these 519 non-tuberculous cases were not easy of recognition or differential diagnosis can be attested by the fact that the majority were sent through other clinics and from competent observers. A certain number, of course, were referred from the various philanthropic societies and other lay organizations, from whom we also derive many of our positive cases. To be exact, 148 of these negative cases were sent to us from the Board of Health; 110 from the medical clinic of our own dispensary; from private physicians, 16; from other tuberculosis clinics, 23; from Board of Health nurse, schools, and school inspectors, 5; from churches, settlements, and social workers, 23; from the United Hebrew Charities, 34; and the Charity Organization Society, 25; from sanatoria and convalescent homes, 3; and from other patients, 31. Twenty-four applied for examination or treatment on their own initiative. The source of 69 of these cases was not given on the charts.

The only conclusion to which a study of these cases has brought us is the familiar and often repeated caution not to make a diagnosis hastily upon insufficient data or too brief a period of observation. The number of apparently negative cases with positive sputum, as well as those in whom a positive sputum or definite signs were only detected after repeated examinations, would alone justify this caution. Furthermore, the difficulty of recognizing incipient tuberculosis, either alone or in combination with other conditions, makes our conclusion too obvious for further emphasis.

I wish to make acknowledgment to Drs. N. G. Seymour and Max Fladen for assistance rendered in collecting the data used in this report.

22 Montgomery Street.

Primary Tuberculous Cystitis.—Gli Virghi states that although in many cases tuberculosis of the bladder is secondary to tuberculosis of the kidney or prostate, still in a considerable number of cases it may be shown to be primary in the bladder. These cases are quite curable by local applications to the bladder combined with attention to hygiene and diet such as is given in tuberculosis elsewhere. The bacilli carried in the circulation directly to the bladder cannot determine a specific affection unless they find a susceptible soil for their action produced by a catarrhal lesion. The principal clinical forms of tuberculosis of the bladder are that depending on renal or prostatic disease, the primary vesical form, and that produced by contiguity, or ascension of the bacilli from the genital organs. The principal symptoms are hematuria, never very prolonged, and due to congestion of the bladder, pain, which is often extreme, preventing cystoscopy and catheterization, and urinary symptoms. There is pus in the urine, but in less amount than is found in abscess of the kidney. Frequent micturition, nocturnal enuresis, and in the early stages an increased amount of urine, with incomplete retention, may be found. The urine remains acid in reaction, the bacteriological examination is interesting, while the chemical examination is of little value. There is present an increased number of leucocytes, which are polyhedral, dentated, or prolonged. Cystoscopy shows in primary cases congestion about the mouth of the bladder, while in renal tuberculosis the congestion is around the mouth of the ureters, and the tubercles are placed there. The author's treatment is local and although it lasts some time it results in a cure. He also attends carefully to the general health. Locally he evacuates the bladder completely, and then injects analgesic and antiseptic solutions, using corrosive sublimate with cocaine once daily. This lessens the pain and cleanses the bladder.—*Giornale Internazionale delle Scienze Mediche.*

EFFECT OF DRUGS ON THE OPSONIC INDEX.

WHEN the opsonic doctrine was first made public it was freely prophesied that drug therapeutics would have to be completely rewritten. We believe that Wright went so far as to state that no remedy could be shown to act either favorably or unfavorably in disease unless it raised or lowered the opsonic index. Prominent homeopathists saw here a long-wished-for opportunity to employ an external checking system for their system of therapeutics. It is evident that no widespread concerted or systematic effort is likely to be made in this field, for the technical difficulties are very great and the proverbial "two thousand" positive results believed to be necessary to overantagonize the combined sources of fallacy in observation require a long time for their accumulation and digestion. It is almost certain that this vast problem will only be attacked piecemeal, when particularly favorable conditions are at hand, and when the immediate problem to be solved is one unusually well suited for a demonstration at will.

Professor Strubel of the Opsonic Laboratory of the Royal Veterinary High School at Dresden (*Berliner klinische Wochenschrift,* June 3) appears to have made some peculiarly happy discoveries in this field. Starting with the knowledge that bromides and iodides cause acne in a large proportion of cases, and assuming that this acne must come about because the resistance to the action of pyogenic cocci is diminished by the drugs, he was able to show that a single large dose of sodium bromide or iodide was able to depress the opsonic index within one hour's time. The index rose to its normal height somewhere from 6 to 52 hours later. The depressing effects of continuous administration of these substances on the index may readily be imagined. Strubell now made the important discovery that a staphylococcus vaccine exhibited at the same time to a subject sensitive to iodine and bromine would antagonize the development of the acne. He then inquires whether this depressing action is due to chemical or physical causes. Sodium chloride, even in very large doses, did not affect notably the opsonic index to staphylococci, while large doses of urea depressed it temporarily. It is evident that large doses of salts have *per se* some influence, however slight and transitory, on the opsonic index, but in order to explain iodic and bromic (he might have added chloric) acne some special causal moment is present, dependent on the halogen component.

The known bactericidal properties of arsenic and the fact that Fowler's solution can to some extent antagonize bromic and iodic acne led Professor Strubell to test it in regard to its action on the opsonic index. Experiments by the author and his staff on their own persons appeared to show that Fowler's solution raised the opsonic index not only against the staphylococcus but against the tubercle bacillus as well. A few tests of salvarsan seemed to show that its marvelous activity in certain directions cannot be due to any general property of improving the opsonic defence. As far as the author has gone he sees no clean-cut evidence of specific activities. Certain substances depress, others elevate the opsonic index. This fact will have to be added to what we already know of the action of a drug. If a medicament lowers the opsonic index for a given germ, an antagonist should be given. If we have to give potassium iodide we may have to exhibit staphylococcus vaccine (or Fowler's solution as of yore).

SELENIUM IN AN OLD ROLE.

THE demonstration by Fournier d'Albe at the Optical Conference Exhibition in London, June 25, 1912, of the remarkable properties of the "optophone," an instrument by means of which the blind can be made to become aware of the proximity of light or darkness through the agency of sonorous vibrations, directs attention to a property of selenium that has been known for many years and that has already been utilized for similar purposes. The optophone appears to be an adaptation of the photophone which was invented by Alexander Graham Bell in conjunction with Sumner Tainter. One of the properties of the crystalline variety of selenium is its electrical conductivity which increases considerably on exposure to light, especially to the red rays. Professor Bell used the telephone receiver as a means of translating into sounds the electrical variations occurring in selenium in response to successive flashes of light. Sounds could be transmitted without wires over considerable distances by means of the sunbeam reflected from an oscillating diaphragmatic mirror attached to the telephone mouthpiece; the oscillating ray, impinging upon the bit of sensitive selenium in a telephone receiver, caused electrical changes which were in turn translated into sonorous vibrations. It was subsequently shown that other substances, such as lampblack, could be substituted for the selenium. Later Mercardier found that different parts of the spectrum produced different sonorous effects. Bell, in amplifying these experiments, showed that the intensity of the sound increased as the telephone receiver was moved from the violet into the ultra-red portion of the spectrum, corresponding to the increase in the heat waves and showing that these are responsible for the sonorous effects. These observations were utilized in the invention of the spectrophone, by means of which bands of sound and of silence are produced to correspond to the colors and absorption bands of the spectrum and

by means of which even the invisible portion of the spectrum can be analyzed.

The press dispatches from London state that the optophone is contained in an oblong box twenty-six inches long and eight inches deep. A blind man held this in one hand and in the other held a cardboard cylinder which was moved slowly before him while being pointed toward the window. By means of the sudden changes of sound in the telephone receiver he could count the number of persons that were standing between him and the window. It is suggested that future developments of this instrument may enable the blind to distinguish by means of audition the shapes of objects and even large print.

Whether the optophone will ever be of any real practical value to the blind is extremely doubtful. The idea is preposterous that this instrument "makes light audible." By translating radiant energy into sonorous effects it may enable the blind, by means of the association of ideas, to recognize changes in the external world which he is already able to appreciate by means of the unaided ear and a well-developed sense of touch. He does not need the optophone to apprise him that he is near an open window, for his acute hearing will enable him to distinguish its proximity by means of the sounds transmitted from the street, and his skin will feel the coolness of the outer air or the warmth of the sunshine. It does not take him long to detect the presence of other individuals in the room. The optophone provides the blind with a roundabout means of distinguishing light from darkness, for which faculty he is abundantly equipped by means of his intact senses and his power of association of ideas. It is to be hoped that human ingenuity will eventually find some use for the optophone other than that of a curiosity.

GRADUATED LABOR IN THE TREATMENT OF THE CONSUMPTIVE.

Although statistics regarding tuberculosis are occasionally somewhat confusing, and it is difficult to say exactly how great progress is being made toward the control and eradication of the disease, it would seem to be a sound statement to make that pulmonary tuberculosis generally is showing a slight decrease in almost all parts of the civilized world. Methods of treatment now appear to have been evolved which meet the exigencies of the situation in a satisfactory manner. A combination, or rather a cooperation of the dispensary, the sanatorium, and the hospital treat and care for those afflicted with pulmonary tuberculosis in the way best adapted to the individual and so that the disease shall spread as little as possible. There is, however, not much new to be said concerning tuberculosis, as Adami pointed out in his presidential address a short time ago before the annual meeting of the Canadian Association for the Prevention of Pulmonary Tuberculosis in Toronto. But there is one feature of the situation which is especially worthy of earnest attention, the need for sending patients out of sanatoriums able to earn their living and not to be a drag upon their family and relatives and a menace to the community. This is one of the hardest problems to solve successfully, so far as the tuberculous are concerned. It is a notorious fact that sanatoriums are frequently compelled to discharge their patients before they are in a condition to bear well the buffets of the world. According to C. D. Parfitt it has been estimated that 75 per cent. of tuberculous patients leave sanatoria or health resorts before the disease is arrested and that 98 per cent. of all patients have to be treated at home.

Oliver Bruce of London, England, who read a paper at the same meeting, holds that much can be done at the sanatorium itself in fitting the consumptive to take his part in the world of work, and he demonstrated the manner in which he believes this result can be brought about. He is a follower of Wright, and has brought Wright's discovery of opsonin into the service of the tuberculous. Opsonin is a protective substance and makes for health and thus it is obviously desirable to raise the quantity present in the serum of all infected people. Rest first and graduated labor afterwards, according to Bruce, have this effect. It is found in the case of a person with tuberculosis that when the temperature is high his opsonic index is low and *vice versa*. The opsonic index varies inversely with the temperature, and as in regulating the amount of exercise to be prescribed in graduated labor, some guide is necessary to show the amount of protective substances which are being elaborated as the result of the exercise, and as it would be too tedious to take the opsonic index as a guide, the knowledge as to how the opsonic index varies with the temperature permits the substitution of the temperature chart for the index. There are now two main facts to work on, Bruce said, (1) that the amount of opsonin or antibody in the blood can be raised by exercise and (2) that the temperature chart and feelings of the patient are a sufficient guide to an experienced observer as to whether the amount of exercise prescribed is too great or too little.

Paterson of England, it is claimed, was the first to find out and to put the discovery into practice that graduated exercise is an excellent mode of controlling tuberculosis and of rendering certain of its subjects selected for the treatment able to take their places in the working world after a prescribed course. Bruce and others have put the treatment on a scientific basis which Paterson had not done. Indeed, Bruce claims that the graduated labor system of treatment is an advance in the scientific care of the consumptive. It aims at raising the amount of antibacterial substance in his blood to as high a degree as possible and keeping it there by gradually increasing doses of tuberculin. Emphasis is laid on the fact that the supervision of consumptives being treated by means of graduated labor must be left in the hands of a person experienced in knowledge of the opsonic index. Bruce stated that results from the treatment of consumptives by graduated labor have been remarkably encouraging. Some patients, indeed, when on the final grade of labor and ready to be discharged, had indices which never varied from the normal, however hard the work, and in the last grade the work

is of the very hardest kind. The reason for this is that when the final grade is reached the lesion is so shut off from the blood stream by fibrous tissue that no toxin can be poured into the circulation and consequently there is no need for the formation of antibodies above the normal amount. Bruce thinks that such patients are, in the true sense of the word, cured—that he obtains a true clinical cure and not a temporary improvement or even an economical cure.

Cancer in Scotland.

Scotland is a small country, but nowhere in the world, not even in Germany, which has recently been so extravagantly lauded by a Carnegie Foundation investigator for its thoroughness and achievements in scientific research, is medical education at a higher standard or are medical men more able and progressive. Consequently the paper read recently before the Royal Society of Edinburgh by Sir George Beatson on the cancer statistics of Scotland from the year 1861 to 1900 is worthy of careful consideration. In the last decade considered, 1891-1900, cancer accounted for 30,908 deaths, or 3.95 per cent. of the total. The mortality from cancer between the decades 1861-1870 and 1891-1900 increased from 3.964 to 7.274 per 10,000 people living, the rate of increase being accelerated from decade to decade. Dealing with the distribution of cancer Beatson stated that no general conclusion could be drawn as to the incidence of cancer in districts. The principal towns compare unfavorably with other districts, and among them Edinburgh stands above and Glasgow below the others. In conclusion, he confessed that the statistics did not tend to any definite results, apart from the fact that an increase in the disease, especially as affecting males, was proven. It also seemed clear that cancer was not affecting young people more frequently than formerly, in spite of the assertions of Mitchell Banks and others. The fatal incidence period in women is from 35 to 45, and in men from 45 to 55, corresponding with the different site of the disease in the two sexes. Cancer as a disease occurs not in the decline of life but on the cessation of reproductive life. Climate and geological conditions do not affect the question. Whether so-called "cancer homes" are instances of coincidence or not is not settled. The only preventive measure which suggests itself to Beatson as of any value is notification which would give more accurate information as to where the disease arises. One other thing is needed in Scotland, and that is research work on the disease, special laboratories, clinical research in cancer hospitals, and systematic investigation generally into the causes, prevention, and treatment of malignant growth. The conditions in Scotland as regards cancer appear to be similar to those in most civilized lands. Statistics tend to show that the disease is increasing, although the very fact of keeping statistics is in itself a means of magnifying the menace of cancer. As for researches into the origin of cancer, the best that can be said is that the mystery gives promise of solution at no very distant day. With regard to treatment, too, the surgeons are probably quite correct when they contend that operation when such is possible is the only method at present known for curing cancer, but even then a return is far from unlikely.

Spreading the Upper Jaw for Mouth Breathing.

That a high palatal arch is naturally associated with a deflected nasal septum is well known and this associated deformity is one of the commonest causes of mouth breathing. In the high, narrow palate it is also common to find the teeth imperfectly aligned, so that when the upper teeth are spread by wearing the brace employed by the dentist, it is easy to understand that in the child the spreading of the upper jaw would have a tendency to flatten the high palate and correct the septal deformity and incidentally to facilitate normal nasal respiration. Landsberger has made a study of the entire subject of the influence of the teeth on the development of the nose. He has noted among other data that defective development of the teeth tends to cause hypertrophy of the turbinal bones. Again, if the *anlage* of the teeth is seated too far inward, there results a deviated septum and narrowing of the respiratory fissure, with formation of a high palate. Several years ago the author began to employ a special apparatus for the relief of this condition. At a recent meeting of the Berlin Laryngological Society (*Berliner klinische Wochenschrift,* June 10) Sturmann announced that he had recently employed the resource in the case of a youth who had marked septal deformity and unusually high narrow palate. After the patient had worn the brace for two and a half months Sturmann was surprised to find that the palate and septum were practically normal. There was none of the recession of the front teeth which might occur in theory. This resource seems worthy of more extensive trial.

The Riddle of Trypsin.

The behavior of trypsin is a never failing source of interest to the physiologist and clinician, and the more we learn of it the more incomprehensible it appears. Inert when first secreted it becomes activated by various agencies, notably the intestinal secretions, into a powerful enzyme, attacking all the types of nutriment but unable to attack the intestinal mucosa, and apparently powerless against intestinal parasites. Nevertheless it quickly attacks various living tissues with which it accidentally comes in contact, as the unprotected integument in pancreatic fistulæ, and the omental fat in pancreas disease (causing fat necrosis). As a rule it is unable to exist in the blood, an antisubstance being produced (antitryptic reaction); but it often appears in the urine. Thrown directly into the circulation it has been accused of setting up a toxic syndrome. At the recent session of the German Congress for Internal Medicine (*Muenchener medizinische Wochenschrift,* May 23), Kirchheim announced that trypsin cannot attack the urinary mucosæ, but that if it is injected beneath the epithelial layer the entire thickness of the wall of the passage becomes necrotic. The mucus secreted is the substance which confers the immunity, and not the epithelium, as he shows by crucial tests. No doubt it is also the intestinal mucus which binds the trypsin and prevents it from attacking the mucosa. In discussion which followed Kirchheim's announcement Schittenhelm stated that absolutely pure trypsin may be thrown into the blood stream in large amounts with impunity, for all the toxic action of this substance, he said, was wholly due to various adherent impurities.

News of the Week.

Typhoid Carrier.—The State Hygienic Laboratory of the University of California has discovered in a sailor on the ship *Acme* a typhoid carrier who is thought to be responsible for twenty-seven cases of typhoid fever which have occurred on the ship in the last three years and a half. The sailor in question suffered from the disease four years ago and was discharged from the hospital as cured. As he had had nothing at all to do with the provisions or cooking on the ship it is thought that the infection was transmitted by means of a common drinking cup used at a water cask on the deck of the ship. Of the twenty-seven cases thought to be traceable to this source of infection four were fatal.

Death Rate Low.—For the week ending June 22, 1912, the death rate in New York was 12.16 per thousand, and the total number of deaths 1,206, a considerable decrease as compared with the same week of last year when the total number was 1,273 and the rate 13.33. For the first twenty-five weeks of this year the rate was 15.17 per thousand, as compared with 16.34 during the same period of 1911. Of the total number of deaths during the week 215 were of children under 1 year, and 343 under 5 years, and 200 of persons 65 years of age and over. Heart disease caused 168 deaths, an increase of 10; pulmonary tuberculosis 155, a decrease of 5; kidney diseases 111, an increase of 28, and lobar pneumonia 72, an increase of 20. In most of the other important causes of death there were considerable decreases.

Free Milk Station.—The first free milk station in Jersey City, N. J., where modified milk will be supplied to mothers unable to pay for it, will be open in the Whittier House on Grand street after July 1.

Psychopathic Hospital.—The new Psychopathic Hospital in Boston was opened for inspection on June 19. The building is four stories high, of brick with terra cotta trimmings, and includes every possible convenience for the treatment of patients, as well as accommodations for a large medical library and laboratories for chemical analyses, etc. The staff of the hospital includes Dr. E. E. Southard, professor of neuropathology in the Harvard Medical School; Dr. H. M. Adler, chief of staff, a graduate of the College of Physicians and Surgeons, New York; Dr. E. S. Vosburgh, executive assistant, a graduate of the Jefferson Medical College, Philadelphia, and Dr. A. W. Stearns, a graduate of Tufts Medical College, Boston.

A Mission Boat.—The schooner yacht *Fleur de Lys* has been presented to the Dr. Wilfred Grenfell Missionary Association by Dr. Lewis A. Stimson of New York, to be used in connection with the work of the Labrador missions.

Connecticut Health Board.—The report of the Connecticut State Board of Health shows that during the month of May there occurred 1,356 deaths, this being a little above the average for the month for five years. The death rate per thousand was 14.8 for the large towns, 14.5 for the small towns, and 14.7 for the whole State.

Hookworm in Alabama.—The director of the hookworm commission in Alabama, Dr. W. W. Densmore, reports that since January 1 hookworm infections have been reported in 3,588 cases. He believes that had it been possible to secure accurate returns from all the physicians in the State this number would have risen to nearly 12,000.

Dr. Carrel in France.—The report made to the French Academy of Medicine in Paris by Professor Pozzi on the results of Dr. Alexis Carrel's experiments in tissue cultivation has created a profound impression in France, and has been received with about equal enthusiasm and scepticism, judging from the newspaper reports. It has been suggested by some of the leading biologists that as these results, if authentic, form the greatest scientific advance of the generation and so cannot be accepted without the fullest proof, a deputation of French biologists be appointed to visit the Rockefeller Institute and determine for themselves that Dr. Carrel's claims are well founded. This proposal has been warmly received and is very likely to be carried out in the near future.

Yale Medical School.—In his annual report President Hadley of Yale University announces that a tentative agreement has been entered into with the New Haven Hospital by which the Yale Medical School will have all the rights of nomination of attending physicians in the hospital and the right to use the hospital for teaching purposes, provided the University agrees before July 1, 1914, to set aside a fund of $600,000, of which $100,000 shall be used to build a clinical and pathological laboratory in connection with the hospital, and the other $500,000 be used to endow it. This arrangement is considered highly advantageous to both parties, and it is to be hoped that it may soon be carried into effect.

Syracuse University.—The Dean of the College of Medicine of Syracuse University reports the following additions to the corps of instructors: As assistant professor of bacteriology, Dr. Leverett Dale Bristol, Johns Hopkins Medical School, 1907; as instructor in the department of histology, Dr. Earl V. Sweet, Cornell University Medical College, 1910; as instructor in surgery, Dr. Albert G. Swift, Syracuse, 1902; as instructor in pathology, Dr. John W. Cox, Syracuse. At the suggestion of the dean, Colgate University has signified its intention of permittting students to take the senior year in a registered medical college *in absentia*, such students to receive the bachelor's degree upon the presentation of a certificate from the college of medicine attended to the effect that his work has been done satisfactorily.

Charitable Gifts.—By the will of the late Mrs. Caroline Butterfield the Children's Aid Society of New York receives a bequest of $25,000 for a "health home" to be named in memory of her son, Frederick F. Butterfield. The New York Orthopedic Dispensary and Hospital also receives a bequest of $5,000 for the endowment of a free bed in memory of her son.

Through a decision recently handed down by the Supreme Court of Massachusetts, the Massachusetts General Hospital of Boston will receive the sum of $60,000, the amount of a bequest made to the hospital in the will of the late Mrs. Sarah Cazenove, who died thirty years ago. The will has been contested by relatives of the testator.

The Montefiore Home for Chronic Invalids has received gifts amounting to $200,000 to be used in the erection of a private pavilion in connection with the new home now under course of construction at 210th street and Gun Hill Road, New York. This will be the first private hospital for chronic invalids in the city.

The Kenosha Hospital of Kenosha, Wis., has received from Mrs. Ella F. Allen a gift of $10,000 to be used for the maintenance of a room in the hospital to be known as the Charles W. Allen room.

By the will of the late Mary E. Irwin of Philadelphia, the sum of $3,000 is bequeathed to the Children's Seashore Home at Atlantic City for the establishment of two beds as a memorial to her parents.

Col. Gorgas Honored.—The trustees of the *American Medicine* Gold Medal Award have conferred the medal for 1912 upon Dr. William C. Gorgas, Ancon, Panama, as the American physician who, in their judgment, has performed the most conspicuous and noteworthy service in the domain of medicine during the past year.

Dr. David F. Atwater of Springfield, Mass., is the oldest living graduate of Yale University. He is now in his ninety-fifth year and was graduated from the University in 1839 and from the Yale Medical School in 1842.

Dr. E. F. Bashford, director of the Imperial Cancer Research Fund of London, has accepted an invitation to deliver the Middleton-Goldsmith Lectures of the New York Pathological Society in this city next October. The exact dates and the title of the lectures will be announced later.

Dr. Eugene L. Opie, professor of pathology in Washington University, St. Louis, has been appointed dean of the Medical School to succeed Dr. George Dock, who resigned recently in order to devote his entire time to his professorship of medicine and to research work.

Dr. Charles Baskerville, professor of chemistry in the College of the City of New York, has been awarded the Edward Longstreth Medal of Merit by the Franklin Institute of Philadelphia for his investigations in the chemistry of anesthetics.

Dr. Duncan W. Blake, Jr., has been elected medical inspector of the public schools of Gloucester City, N. J.

Dr. William Kelly Simpson, professor of laryngology at Columbia University, has recently been appointed consulting laryngologist to the Presbyterian Hospital, New York City.

Medical Society of the State of North Carolina.—The annual meeting held in Hendersonville during the third week of June was brought to a close with the election of the officers for the ensuing year, as follows: *President,* Dr. John P. Munroe, Charlotte; *Vice-Presidents,* Dr. Fletcher R. Harris, Henderson; Dr. E. S. Bullock, Wilmington, and Dr. L. B. Morse, Hendersonville; *Treasurer,* Dr. Herbert D. Walker, Elizabeth City. Morehead City was chosen for the next meeting place.

North Carolina Health Officers' Association.—The second annual session, held in Hendersonville on June 19, closed with the election of officers, which resulted as follows: *President,* Dr. Lucius N. Glenn, Gastonia; *Vice-President,* Dr. George M. Cooper, Clinton; *Secretary-Treasurer,* Dr. Watson S. Rankin, Raleigh.

Chicago Medical Society.—The following officers were elected at the annual meeting on June 19: *President,* Dr. Jacob Frank; *Secretary and Editor,* Dr. Patrick J. H. Farrell.

American Institute of Homeopathy.—At the convention held recently in Pittsburg, the annual election of officers resulted as follows: *President,* Dr. Wilbert B. Hinsdale, Ann Arbor, Mich.; *Vice-Presidents,* Dr. B. Stout, Jacksonville, Fla., and Dr. Mary E. Banks, Chicago; *Treasurer,* Dr. T. Franklin Smith, New York; *Secretary,* Dr. J. Richey Horner, Cleveland, Ohio.

Glynn County (Ga.) Medical Society.—At the annual meeting held in Brunswick on June 17 officers were elected as follows: *President,* Dr. Robert E. L. Burford; *Vice-President,* Dr. George W. Blanton; *Secretary-Treasurer,* Dr. John W. Simmons.

Obituary Notes.—Dr. Henry B. Deale of Washington, District of Columbia, a graduate of the George Washington University, Department of Medicine, in 1887, and a member of the Medical Society of the District of Columbia and of the Society of Nervous and Mental Diseases of Washington, died suddenly at his home of neuralgia of the heart on June 19, aged 50 years.

Dr. Albert F. McVety of Toledo, Ohio, a graduate of Queen's University, Medical Faculty, Kingston, Ontario, in 1887, a member of the American Medical Association, the Ohio State and Lucas County Medical Societies, and the Royal College of Surgeons, London, died at his home suddenly of acute indigestion on June 9, aged 58 years.

Dr. R. Bruce Burns of Philadelphia died at Atlantic City on June 15, after an illness of three years, at the age of 62 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1871. He was one of the founders of the Frankford Hospital as well as one of its visiting physicians.

Dr. Harry H. Harrison of Jackson, Miss., a graduate of the Kentucky School of Medicine, Louisville, in 1891, and a member of the Kentucky State and Hinds County Medical Societies, died at his home after a long illness on June 14, aged 51 years.

Dr. Manuel R. Morena of Tampa, Fla., a graduate of the Medical College of the State of South Carolina, Charleston, in 1878, and an expert on yellow fever, died at his home on June 17, aged 66 years.

Dr. Homer V. Reynolds of Marietta, Ga., a graduate of the Jefferson Medical College, Philadelphia, in 1869, and a member of the American Medical Association and the Georgia State and Cobb County Medical Societies, died on June 18 in a sanatorium in Atlanta, aged 64 years.

Dr. W. F. Mueller of Denison, Ia., a graduate of the University of Marburg, Germany, in 1869, died at his home recently.

Dr. George P. Hanawalt of Des Moines, Ia., a graduate of the Georgetown University, School of Medicine, Washington, in 1864, a member of the American Medical Association, of the Iowa State Medical Society, in which he served as secretary in 1871, and as president in 1880, and of the Polk County Medical Society, a veteran of the Civil War and a former surgeon in the National Guard of Iowa, retiring some years ago with the rank of brigadier-general, died at his home on June 19, aged 76 years.

Dr. William Wilson Walter of Leavenworth, Kan., a graduate of the University of Pennsylvania, Department of Medicine, in 1883, and a member of the Kansas State and Leavenworth County Medical Societies, died at his home after a long illness on June 12, aged 51 years.

Dr. William E. Gordon of Pocahontas, Ill., a graduate of the Washington University Medical Department, St. Louis, in 1890, died at his home on June 19, after a long illness.

Dr. George F. Lucas of Currie, N. C., a graduate of New York University Medical College in 1870, and a member of the North Carolina State and Pender County Medical Societies, died at his home suddenly on June 17.

Dr. Henry J. C. Sieving of St. Louis, Mo., a graduate of the Beaumont Hospital Medical College, St. Louis, in 1897, and a member of the American Medical Association and the Missouri State and St. Louis City Medical Associations, died suddenly at his home on June 21, aged 53 years.

Dr. Robert J. Devlin of New York, a graduate of the College of Physicians and Surgeons, New York, in 1881, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Society of the Alumni of St. Luke's Hospital, and the Medico-Surgical Society, dermatologist to the Northern Dispensary, and consulting physician to the French Hospital, died at his home on June 26, aged 52 years.

Dr. Juan Garcia Puron, who died in his native town, Llanes, Asturias, Spain, on June 9, aged 58 years, was for many years at the head of the Spanish Department of D. Appleton & Company, New York. Dr. Puron took his medical degree in Spain and when quite a young man went to Mexico to practise medicine and advance the cause of education. While there he became interested in politics and was one of the leaders in a revolution against the Government of Diaz, for which he was banished from the country. Coming to the United States he practised his profession for a time and then took up literary work. A few years ago he returned to Spain.

Correspondence.

THE CARE OF TUBERCULOUS CATTLE

To the Editor of the Medical Record:

Sir:—It is astonishing to consider how differently the disease known as bovine tuberculosis is being handled in this country compared with the methods of handling infectious diseases in human beings, particularly those which are known to be readily transmissible. In suppressing smallpox, scarlet fever, or diphtheria among human beings one would not dream of making an appropriation of money and offering to pay this to such persons as voluntarily submit themselves to a test for these diseases, leaving all others afflicted with the disease to roam at large unrestrained. If there is any one thing which bacteriologists, health officers, and physicians know is positively common to infectious diseases it is that they are transmitted from persons already infected to new persons who have not yet been infected. The bacteria of infectious diseases are carried about on the bodies of men and of animals, and in this way are distributed as the man or animal moves from place to place. In taking measures for the suppression of smallpox, diphtheria, or scarlet fever, it is fully recognized that this wandering of the infected person must positively be checked or the disease will spread. Therefore a strict quarantine is maintained over the persons known to be sick and they are prevented from coming in contact with those who are well until the disease has run its course and they cease to be a menace to others. In the case of tuberculosis in human beings, while it is well known that this disease also is transmitted from those who are sick to those who are well, yet, becaue it is so widespread and because it has not been looked upon as so serious a disease as the others above mentioned, no attempts have been made to maintain a strict quarantine over infected persons. Sanitary precautions can be exercised by the majority of human beings which will prevent the transmission of this disease without quarantine.

In considering tuberculosis among cattle, however, we have to face a different state of affairs. Here it is obvious that the individual has not sufficient intelligence to carry out any sanitary precautions for herself. An infected dairy cow is certain to carry her infection and to transmit the disease to other animals if allowed to mingle with them. While this fact is well known, the action taken by our State authorities entirely ignores its existence. State laws in general have taken only two precautions. The first has been the establishment of quarantine against cattle imported from other States; the second has been to offer to pay part of the value of such animals as are destroyed after having been proven tuberculous by the application of the tuberculin test. The State laws, however, have made the tuberculin test optional. This has left the dairy cattle in the State at entire liberty to be transferred from farm to farm, from county to county, and from one part of the State to another, with no restrictions whatever. Consequently we find States some of which have made large appropriations of money amounting to several hundred thousands of dollars, spending the same in paying for the slaughter of dairy cattle, while the number of animals suffering from bovine tuberculosis is constantly recruited by the wanderings of infected cattle from herd to herd and from county to county throughout the State. This is a foolish waste of money. We cannot dodge the issue. Either bovine tuberculosis is a disease which should be suppressed by the proper application of State laws, or it is one which State laws cannot control. If it is to be brought under control it certainly must be treated as other infectious diseases are treated, namely, by quarantine. If those animals which suffer from tuberculosis are not permitted to leave the premises on which they are stationed, then the disease will cease to be transmitted from one place to another. There are few dairy farmers even among those opposed to the application of the tuberculin test who would buy an animal afflicted with tuberculosis if they had knowledge that such was the case. I doubt if there is a buyer in existence who would voluntarily accept an animal to be used for dairy purposes knowing the same to be suffering from tuberculosis. The majority of buyers accept animals on the assumption that they are free from this disease, even though the test has not been applied. It would therefore be no injustice to the buyer of cattle if the law should prohibit the transfer or the sale of an animal which had not been proven free from tuberculosis by the tuberculin test. The owner of tuberculous cattle might object to the enforced quarantine on the ground that he is prevented from selling his tuberculous cows. He is not likely, however, to receive much sympathy either from the buyer or from any one else on this point. If cows are tuberculous they certainly should not be placed upon the market without being labeled as such.

The slaughter of animals found to be tuberculous is an immense economic loss to the State. It seems probable that a large percentage of tuberculous

cattle under proper conditions would recover from the disease in the same manner that a large percentage of human beings recover. Any one who has attended the slaughter of large herds cannot help being impressed with the fact that many times a large percentage of healthy looking animals in whom but slight evidences of localized disease are found are killed, and their slaughter seems unnecessary. These animals if placed amid proper surroundings and treated by the Bang system would undoubtedly show a large percentage of recoveries.

New York State spends several hundred thousand dollars yearly in paying for slaughtered animals and yet those who have studied bovine tuberculosis believe that it is on the increase at the present time in that State. Either the campaign should be carried on more intelligently or it should be entirely abandoned. As an improvement over present laws I would make the following tentative suggestions:

1. That each dairy farm be quarantined to the extent that dairy cattle are prohibited from crossing the farm boundary just as they are now prohibited from crossing the State line until they have been proven free from tuberculosis by the tuberculin test.

2. That animals offered at public or private sale cannot be so offered until they have successfully passed the tuberculin test.

3. That in the event of the tuberculin test being applied and reacting animals being found, only those shall be slaughtered which are obviously diseased as shown by physical examination.

4. That animals which are obviously diseased as shown by physical examination by a competent veterinarian shall be slaughtered and paid for as under State appropriations provided by State laws in the past.

5. That reacting animals which show no obvious signs of disease by physical examination shall either be kept separate on the farms where they reside from healthy animals, or that the State set aside certain farms as sanatoriums for the treatment of these cases, with a view to securing the recovery from the disease of a large percentage of the animals.

CHARLES E. NORTH, M.D.

The Survival of the Premature Infant.—L. Tissier presents a study of the viability of premature infants with reference to their legal status in various countries. In Germany the state of maturity of the fetus in order that it may inherit is not defined, but proofs that the child had lived must be given; in Spain it must have lived for 24 hours completely separated from its mother; in England it must have given some signs of life after birth; in France 140 days of intrauterine life must have elapsed in order for the child to have been viable. Theoretically it is generally accepted that the child is not viable until the sixth month and cannot inherit. The author describes a case under his observation in which the child was born on January 4, in the Charité Hospital, the weight being 990 grams, and length 31 centimeters; the eyes were closed, the nails were incompletely formed, the body was red, and the movements were hardly perceptible. The infant was at first fed with a stomach tube, and later began to swallow and suck. The last menses occurred about the end of June. The patient thought conception occurred about July 14. Thus the child, still alive at the time of writing, and 36 days old, had had five months and twenty days of intrauterine life. The law does not provide for such a contingency.—*Gazette des Hôpitaux.*

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL SUNDAY—KING'S BIRTHDAY HONOR LIST—QUEEN AT EXHIBITION OF MISSIONS TO ABORIGINES—RESEARCHES AUTHORIZED BY GOVERNMENT BOARD—DEMENTIA—ANNUAL CONFERENCE ON PREVENTION OF CONSUMPTION—GENERAL MEDICAL COUNCIL—OBITUARY.

LONDON, June 15, 1912.

HOSPITAL Sunday was the opening day of the week. The King and Queen attended the morning service of St. Paul's, their presence being without ceremony. Dean Inge was the preacher and founded his sermon on the parable of the Good Samaritan. He paid willing tribute to the work of the hospitals, which, he declared, were judiciously and economically managed. The doctors and nurses, he said, "whether they professed themselves His disciples or not, were doing our Lord's work. No more devoted work was being done anywhere."

In the afternoon our medical Lord Mayor and corporation attended St. Paul's in state, together with the Judges. The Lord Mayor with the Sheriffs had attended the morning service at Westminster Abbey, where Canon Pearce urged that recent legislation should not be pleaded as an excuse for omitting this work of charity.

The Bishop of London, preaching at Kensington, described the hospitals as "the air shafts of heavenly charity and sympathy for the purification of our lives, the most complete centers of unselfish activity in this great city, schools of moral discipline, and homes of rest."

To-day the King's birthday is officially celebrated, though not the actual anniversary. A list of honors conferred is accordingly issued—four new peerages, a number of privy councillors, 9 baronetcies and a long list of knights. Among the last are the following members of the profession: B. G. A. Moynihan, F.R.C.S.; J. Bland-Sutton, F.R.C.S.; A. G. Thomas, M.D.; St. Clair Thomson, M.D.; Lieutenant-Colonel Professor Prain, F.R.S. Among Companions of St. Michael and St. George is Andrew Balfour, M.D., director of the research laboratories, London College, Khartoum. Companionship of the Star of India is conferred on Surgeon-General H. R. Stevenson, and the same rank in the Order of the Indian Empire on Lieutenant-Colonel C. H. James of the Indian Medical Service and adviser of the Patiala State. The Kaisar-i-Hind medal for public service in India goes to Dr. Avergal of Madras. Appointments and promotions in the Order of the Bath include Surgeon-Major-General A. F. Bradshaw and Surgeon-General William Babtie. In the Royal Victorian Order Professor Ogston becomes a knight and Mr. Cheatle commander, as does Inspector-General Ninnis M.D., and Mr. Barron a member. Rickman Godlee, president R.C.S., receives a baronetcy.

The Queen opened on Wednesday an exhibition illustrating the work of missions among aborigines who are subjects of the British Crown. There is a court devoted to medical missions in which may be seen complete equipments of dispensaries and hospitals, in contrast with the barbaric implements of witch doctors and the remedies employed in China, India, and other places. There are also exemplifications of the life and habits of different peoples.

The Local Government Board has authorized some medical researches, to be paid for out of the Parliamentary fund for scientific investigations

concerning disease, viz.: (1) As to the distribution of tubercle bacilli in children of two to ten, and the incidence of tuberculosis of different forms in various parts of the country according to age, sex, and other conditions. (2) Continuation of research into arterial degeneration in man by Dr. Andrewes. (3) Joint investigation by him and Dr. H. H. Gordon. (4) Continuance of researcch as to nonlactose ferments in the alimentary canal of infants by Drs. C. J. Lewis, D. M. Alexander, and Graham-Smith. (5) Continuance of Professor Nuttall's investigations on fleas and on the range of flight of domestic and allied flies.

What does the word dementia mean? Dr. Robert Jones tried to elicit opinions on this at the Medico-psychological Association. He himself held there was only one form—primary, its chief characteristic being unemotionalism, though will power and conductivity might be present. Sir Thomas Clouston wrote that the term should be used for incurable, noncongenial states of mind, and new names found for the acute form and the precox. The dominating form was the secondary or sequential, which covered five-sixths of the incurably insane and was the type of all hereditary mental diseases. Adolescent insanity and dementia precox were merely preliminary to it. Dr. Mercier, who also wrote, said he means by the word any degree of mental deterioration, temporary or permanent, whether or not with active manifestations such as delusions or disorderly conduct. A demented person was "unminded" or deprived of some portion of his mind, especially his judgment and intelligence, or of moral rectitude. The term "precocious dementia" implied that in advanced life there was naturally weakening or decay, which might set in earlier than usual. The term partial might imply a degree of failure in all faculties, or to some only, the others being unaffected. In the first sense the term "completely demented" has been used, but if all his mind were lost the patient must be quite unconscious, as one in coma is. In every case of insanity both a negative and positive factor existed. The delusion is not important, but the loss of judgment which would prevent it being entertained; not the outrageous conduct, but the loss of inhibition of conduct which permits that conduct to occur. These losses he calls the unminding or deprivation of mind dementia in the literal sense which he understands by the word.

The fourth annual conference of the Association for the Prevention of Consumption has been held at Manchester. One of the chief discussions was on tuberculosis in childhood. Dr. Raw dilated on the damage of expectoration and also condemned kissing by consumptives. The work done by the Edinburgh School Board in establishing country schools for consumptive children, and improved types of city schools, was illustrated by a lady member of the board. Dr. J. E. Squire said there was little evidence that infection occurred to an appreciable extent in school, but on the other hand there was abundant evidence of the opportunities for infection in the homes of many of the children attending the elementary schools. The presence of a consumptive teacher must be admitted to be a risk, and school teachers suffered from phthisis above the average of the population. Medical inspection should include the teachers.

Dr. Philip said tubercle existed in the majority of school children, and Dr. Priestley estimated that most children became tuberculized by their fifteenth year, but in 22 per cent. its development was indefinitely postponed. Dr. Last, from experience of 800 children, said it was an error to class tuberculosis as acute and fatal in them. It was often very insidious in its approach, and treatment was more hopeful than in adults. These opinions were elicited by a paper contributed by Professor Delapine, who gave the results of his researches during about sixteen years, and exhibited elaborate statistics. Modern teaching, he said, was that tubercle could be conveyed from cattle, contrary to Koch's view. Milk is the most important danger from bovine tubercle. His statistics showed 20 per cent. of fatal cases in children were infected through the alimentary canal, and in 22 per cent. of deaths at all ages infection had been of bovine origin. He estimated 25 per cent. of all children under five had bovine tuberculosis in some form. The relation of the insurance scheme to the disease was discussed at later sittings. The tuberculosis exhibit made a stay at Salford during the sitting of the conference, after which it passed on to Manchester.

The Countess of Aberdeen presided at the concluding meeting and gave an account of the work of the Women's Association for Preventing Tuberculosis in Ireland. She said the deaths from all forms in 1901 numbered 11,679 and in 1911 the number was 9,623, equal to 40 fewer every week. Special courses for studying the Insurance Act were being arranged in the hope it would bring together all the agencies at work in the anti-tuberculosis crusade. Dr. C. Templeton, Medical Health Officer of Health for Dundee, said the act would make it possible for local authorities to carry out a comprehensive scheme for dealing with tuberculosis without unduly taxing their financial resources. Another member thought the work would be less efficiently done when left to State officials. There was some difference of opinion expressed on this point and as to whether the campaign could be continued without imposing an excessive burden on local funds.

The General Medical Council concluded its services on Saturday. In addition to what I reported of its doings in my last, it exercised its disciplinary powers on several other cases brought before it. They were all carefully considered. It was agreed to recognize teaching of preliminary science to a certain extent in institutions duly approved, subsequent to the student passing the preliminary examination in general education. The words pharmacology and therapeutics were substituted for therapeutics, and anesthetics added in the lists of subjects for study and examination. The report of the Educational Committee was received and inserted in the minutes, as were several other reports. Other committees were reappointed, formal business transacted, and a vote of thanks to the president carried with applause.

Liverpool laments the loss of her senior physician, Dr. A. T. H. Waters, who died on Saturday last, aged 86. He had served for a long period in the Northern Hospital and the Royal Infirmary, in which his skill as a physician and clinical teacher were both much admired. He was one of the most influential advocates of establishing the University, and in due course was its Professor of Medicine. His contributions to societies and journals were always worth careful study. He had practically retired from practice for a long time, but in age and impaired health was able to indulge his literary tastes and enjoy the society of his

numerous friends, who regarded him as the highest type of a physician and gentleman.

Dr. Robert N. Hartley, formerly surgeon and ophthalmologist at the Leeds Infirmary, has died at the age of 58. He had suffered from ill health for many years and some fifteen years ago was obliged to retire. He had been prominent among those of the Leeds School who desired to have it made into a faculty of the University, and when that took place accepted the Professorship of Public Health. He suffered from a form of epilepsy which he thought originated in an injury to the head which was inflicted on him in an attempt at robbery. After retirement he devoted himself to every good work open to him.

6. Two New Instruments for Nose and Throat. L. M. Freedman.
7. A Report of Two Cases Reinfected with Syphilis Following Treatment by Salvarsan. J. H. Cunningham, Jr.

1. **The Burden of Feeblemindedness.**—W. E. Fernald states that compulsory surgical sterilization of all defectives is proposed as a radical method for preventing the hereditary transmission of feeblemindedness. At least six States have passed laws authorizing or requiring this operation. In no State, however, has this remedy been applied on a large scale. There are many objections to this plan. The friends of the patients are not willing to have the operation performed. The normal "carriers" of defect would not be affected. The presence of these sterile people in the community, with unimpaired sexual desire and capacity, would be a direct encouragement of vice and a prolific source of venereal disease. Sterlization would not be a safe and effective substitute for permanent segregation and control. It is probable that education in the broadest sense will be the most effective method in a rational movement for the diminution of feeblemindedness. The public generally should be intelligently informed as to its extent, causation, and significance by means of suitable literature, popular lectures, and other means. There is now a great demand for such information from women's clubs, church societies, charitable organizations, etc. General knowledge of this subject in a community will insure the rational protection and control of the feebleminded persons in that community.

2. **Efficiency Tests of Out-Patient Work.**—W. E. Fernald states that the work of out-patient departments is of great public importance, but despite the large sums devoted to it annually, no systematic tests of its efficiency have been devised. The ordinary method of judging out-patient and similar medical work is by the "method of adventitious memory," *e.g.* telling about cases the results of which happen to be known. The proper method of applying an efficiency test is the statistical method, by which a number of cases selected at random are studied as a whole in order to ascertain the different results achieved and the relative proportion of each type. Out-patient departments must determine, first, the results attained with relation to disease, and second, those secured in improving the human beings who come for care. An efficiency test based on these principles leads to the study of a group of patients selected at random, conducted partly by persons trained in social investigation and partly by examination of the medical data secured during visits to the clinic. A study of this type conducted at the Boston Dispensary, upon a group of 116 patients, reveals the social and economic classes to which they belong, their previous medical resources, their present medical and social problems and the medical results achieved. The discussion of so-called dispensary "abuse" has suffered because of lack of social facts secured in this way; and because of consequent absence of recognized standards. In determining the eligibility of patients for treatment, the character of the disease from which the patient is suffering and the provision of medical service in the community for that particular disorder must be considered as well as financial condition. The study of the 116 patients of the Boston Dispensary indicates that in one-third of the cases no result was reached because of the failure of the patients to return for the treatment which the first visit had shown to be required. This is a minimum figure for the medical waste in this group. An increase of efficiency (including the reduction of the percentage of medical waste) depends on various factors, particularly on clinical organization and on an organized follow-up system. Follow-up work, to be most efficient and economical, must be based upon social diagnosis and classification of the patients, and this must be done chiefly by specially trained social workers assigned to service in the clinics under the direction of the physicians. Only by systematic efficiency tests, based on medical and social studies of groups of patients selected at random, is it possible for an out-patient department to organize its work on a basis of maximum efficiency and economy.

3. **Early Diagnosis of Pulmonary Tuberculosis.**—J. B. Hawes, 2d, finds that the evidence from the best sources available is strongly against any proposition that the early diagnosis of tuberculosis is being carried too far. Very few non-tuberculous patients are admitted to sanatoria; there is no evidence that any harm is done, or anything but good accomplished by admitting such patients; the "stigma of tuberculosis" is more a fiction than a fact; homes are not wrecked by sending away the breadwinner who has suspicious symptoms, but, on the other hand, tragedies of the most pathetic nature are daily being enacted on account of hyperconservatism and unwillingness on the part of the physician to make a definite diagnosis and to institute efficient treatment. Finally, while the diagnosis of "tuberculosis suspected" is a perfectly proper and right one to make in many instances, it should be regarded as only a temporary or provisional one, and the patient should be followed up until the diagnosis of his condition can be made definite one way or the other, while in the meantime he is given proper treatment and has the exact situation clearly explained to him.

7. The Rapidly Fatal Institutional Form of Acute Poliomyelitis. J. Van V. Manning.
8. Some Facts Suggested by the Examination of the Children of Tuberculous Patients. C. Blum.

1. **Arthrodesis and Arthrolysis.**—A. Lorenz concludes that if it be admitted that a healthy and painless, though paralytic joint, outvalues a stiff joint (especially in patients condemned to a sitting life), then arthrodesis is justified only at the paralytic shoulder and eventually at the contracted paralytic wrist; the static joints had better be left to mechanical fixation. If an ankylosed joint in favorable position is preferable to a mobile but sensitive and even painful joint without sufficient stability, then it must be admitted that for the moment being, arthrolysis is justified only in the elbow joint and in the jaw. In

judging these difficult questions, one must always be aware that in orthopedic surgery one has no vital indications. One should have faith in his asepsis in operations of vital indications, but should not boast of its infallibility to justify an unnecessary operation.

2. **Sex Issues from the Freudian Standpoint.**—By J. J. Putnam. (See MEDICAL RECORD, May 11, 1912, page 918.)

5. **Dietetic Treatment of Cardiovascular Disease.**—E. E. Cornwall concludes that the most important thing in the treatment of cardiovascular disease is the regulation of the diet. The diet should be regulated so as to supply the maximum of nutrition with the minimum of work for the crippled cardiovascular system. Such regulation means the restriction of the quantity of food to the minimum health ration or less, and the selection of articles which meet the indications presented by the kidneys, the liver, the heart, the gastrointestinal tract, and the general condition and habits of the patient. The diet in cardiovascular disease should be antiputrefactive, it should be to a large extent purin free, from it should be excluded the more fermentable carbohydrates, particularly cane sugar, it should be easily digestible, and it should be sufficiently laxative. The evening meal should always be a light one, and no food or drink should be taken near the time of sleeping. A prophylactic treatment of cardiovascular disease is possible, and consists largely in the regulation, according to the principles above laid down, of the diet of those whose family history or ways of life point to premature cardiovascular degeneration.

6. **Pneumonia as a Complication.**—M. Girsdansky states that it is held by many authorities that primary uncomplicated pneumonia is a self-limited disease, tending to end in recovery; others have stated that in such cases the mortality should be nil. But for pneumonia complicating other pre-existing diseases, no such prognosis is given. The author believes that even in the latter cases when fatalities result, these are due not to the pneumonia, which, when properly treated should always end in recovery, but solely to the underlying conditions. For example, in cases treated for pneumonia complicating cirrhosis of the liver or kidney, Hodgkin's disease, hemiplegia, grave myocarditis, diabetes, carcinoma, advanced senile arteriosclerosis, or extensive pulmonary tuberculosis, when resulting in death, the fatal issue, it seems, is always due, not to the pneumonia, but to the pre-existing conditions. But when pneumonia occurs in the course of an otherwise nonfatal, acute, or chronic malady, the pneumonia in itself does not render the prognosis unfavorable and such cases always terminate in recovery.

7. **Rapidly Fatal Institutional Form of Poliomyelitis.**—J. Van V. Manning states that it was in England that there was first recognized the rapidly fatal institutional type, in which poliomyelitis appears in the form of sudden and deadly asphyxia. Hospitals and institutions were affected seriously with epidemics of this disorder, and an official blue book on the subject was published. The cases tended to occur in small epidemics, in which, after a few hours' illness, death occurred suddenly with the signs of acute asphyxia. The cases were supposed to be occasioned by an inflammation of the cord and brain, as the result of which the vital centers were first attacked. As this form of the disease has not yet been confirmed or negatived by autopsy and pathological examination, it must be considered hypothetical. This should not interfere with prophylaxis of these outbreaks, and the same methods should be advocated and made use of that would be used were the pathological relations established. Obscure knowledge concerning these outbreaks has led to guesswork that would tend to nullify any reasonable method of checking the spread of the disease.

2. **Salvarsan in Syphilis of the Nervous System.**—J. Collins and R. G. Armour present the results of their investigations on this subject. The diseases studied were tabes, paresis, certain forms of myelitis, myelomalacia, encephalomalacia, meningitis, endarteritis, and gummatous formation. Assuming that salvarsan destroys the spirochete when brought in contact with it, the authors state that what they have already learned is that one dose rarely cures the disease, that the intravenous method is preferable for certain reasons, but not so potent as the intramuscular, and that in cases of long-standing syphilis salvarsan must be given repeatedly in many instances in full doses, and sometimes other agencies, such as mercury, must be invoked. The average dose of salvarsan in nervous syphilis, when vitality is not greatly impaired and the blood-pressure is not high, is 0.6 gram. Not more than half of this dose should be given, however, in cases with cardiovascular degeneration and high blood-pressure. It is not the author's experience that organic nervous diseases are best treated by repeated small doses, but that full doses are better with patients that have a fair amount of vitality. Nine cases of paresis were systematically treated with salvarsan and in three great improvement took place though one of these patients died later in convulsions occurring while the patient was apparently in perfect health. While mercury has been for a long time a trusted weapon and practically the only one, salvarsan is far more satisfactory in the treatment of syphilis, though it has not replaced mercury altogether.

4. **Adhesions of the Colon.**—By M. L. Harris. (See MEDICAL RECORD, June 29, 1912, page 1248.)

5. **Uterovaginal Prolapse in Elderly Women.**—G. B. Somers believes that a careful consideration of the conditions involved in the operation for prolapse of the uterus will lead to an acceptance of the following propositions: It is better to preserve the uterus than to remove it. The cystocele complicating prolapse of the uterus is most effectively treated by re-inforcing the anterior vaginal wall. Interposition or vaginofixation best answers the requirements of the operation. In regard to the technique of interposition the author believes that where the operation is applied to severe cases of prolapse, success depends largely on the following points: Amputation of the portio vaginalis, transposition of the cervical stump high in the vault, support of the stump by shortened sacrouterine ligaments, and functional restoration of the perineum.

6. **Incomplete Abdominal Surgery.**—H. G. Wetherill makes a plea for larger incisions and more thorough examinations in abdominal surgery. In operations for appendicitis through a small "gridiron" incision, serious pelvic lesions, gallstones, gastric and intestinal lesions, etc., have been often overlooked and the patient is hardly better after the operation although the diagnosed lesion has been removed. Every one who proposes to undertake abdominal operations of any kind should feel it his duty to be prepared to meet any conditions which may

be found in the abdomen and should not close it up, except in an emergency, until he has ruled out any possible coincident or corresponding pathological condition. Certain noted exceptions to this rule may be admitted, as in operations for intestinal perforation, appendicitis or salpingitis, in which infection would be diffused, or in ectopic pregnancy with rupture, or cesarean section. In such cases a definite diagnosis is usually possible and the emergency is such that the particular trouble diagnosed is alone to be considered. One should remember the frequency of gallbladder disease in women when performing gynecological operations, and that certain pelvic conditions may give rise to profound stomach disorders. Tuberculosis, cancer, enteroptoses, stomach or intesinal perforations, intestinal obstruction, rupture of the uterus, diverticula, gallstones, pancreatitis, etc., may accompany any other condition and complicate any abdominal operation one undertakes. Exact and complete preoperative diagnosis in certain areas of the abdominal cavity can never be made with exactness and this is particularly so in the upper right quadrant of the abdomen.

1. **Moot Points in the Pathology and Clinical History of Pneumonia.**—P. Kidd states that whether pneumonia is excited by the entrance into the body of dried sputum containing diplococci from without, or whether it is to be attributed to autoinfection with germs constantly present in the throat, is still uncertain. It seems somewhat difficult to believe that the continued presence of diplococci in the throat would not lead to the establishment of a certain degree of immunity against infection with the particular strain, whereas the entrance of a different and perhaps more virulent strain of pneumococcus from external sources might, under certain conditions, be able to cause infection. It seems from the early date at which diplococci may be found in the blood and from the clinical evidence that pneumonia so often appears for some days under the guise of a general infection without local manifestations that a septicemic origin supplies the best explanation. But the exact route by which infection of the blood takes place has yet to be demonstrated. Neufeld and Haendel have published the results of their investigations on the origin of the crisis in pneumonia and on the immunizing action of pneumococcal serum. In opposition to Seligmann and Klopstock, they believe that the crisis not only depends on the formation of antibodies, but that these antibodies can be recognized experimentally with certainty, and may even be estimated quantitatively. The antibodies found in the blood of convalescents from pneumonia behave in exactly the same way as those artificially produced in animals. The practical application of pneumococcal serum for therapeutic purposes depends on the preparation of a sufficiently powerful serum and on the rapid introduction of the same into the body in sufficient quantities. For this purpose they recommend as indispensable the intravenous injection of large quantities of serum, which, according to recent experience, is free from danger.

2. **Fluid Exudates and Immunity.**—L. S. Dudgeon presents the results of his investigation of the blood and body fluids in 150 cases of acute and chronic infective diseases occurring in the human subject. It was thought necessary to ascertain the comparative value of the exudates formed during the course of bacterial infections in man, and whether these exudates contained active substances similar to those found in blood serum and possessing the same degree of activity. On the other hand are substances of an inhibitory nature present in these exudates and in blood serum, and, if so, is the action specific or otherwise? If an inhibitory action occurs, is it directly on the leucocytes or on the serum or both? It was also considered necessary to ascertain, as far as possible, the reaction of the exudates, and whether the reaction was directly related to the phagocytic activity of the fluids. In the majority of instances the author found that the body fluids obtained from the infective focus are devoid of opsonin and complement. In one instance there was abundance of opsonin and complement, but the activity of the exudate was much less than that of the autogenous blood serum. The loss of opsonin appears to be complete and cannot in any way be regarded as a specific defect, as in these experiments and in the vast majority which have been made the body fluids were tested with the organism giving rise to the infection from which the patient was suffering, and another organism in no way related to the disease. In some acute infections of very short duration and in certain bacterial conditions affecting the serous cavities the body fluids are found to be as potent as blood serum. The author's experiments clearly demonstrate the activity of the body fluids in many acute infective processes. In three cases of acute arthritis it was found that the serum from the joint cavity in each case contained a large amount of opsonin and complement. The experiments are sufficient to show that the body fluids which contain complement also contain opsonin, and the opsonin is present for bacteria other than those which give rise to the disease from which the patient is known to be suffering.

3. **The Presence and Intensity of Syphilis in the Past.**—N. Moore states that the poem of Hicronymus Fracastorius which was published at Verona in 1530, furnishes evidence that at the time the poem was written there was prevalent an hypothesis that syphilis was then of recent origin. There is no evidence that syphilis was imported from America following the discovery by Columbus. No certain references to syphilis are to be found in the general Greek or Latin literature. No undoubted syphilitic lesions have been discovered in the vast collection of human remains belonging to several thousand years of Egyptian history. In the numerous writings of Galen there is no reference to any of the nervous diseases that are caused by syphilis. There is reason to believe that syphilis first made its appearance in Europe at the end of the fifteenth century.

5. **Syphilis d'Emblée.**—J. E. Lane states that this term connotes an infection that may occur directly into the blood stream without the formation of a chancre. A far better term is cryptogenic syphilis, signifying syphilis of hidden origin. This form of the disease is found especially in members of the medical profession. In two cases reported by Jullien of Paris, this observer calls attention to the early date at which the blood of syphilitic subjects becomes infectious, before the appearance of any secondary eruption, and even before that of the initial lesion. More than two years ago Waelsch made a communication on this subject in the *Münchener medizinische Wochenschrift*, and related several cases in which medical men had contracted the disease in this manner. Strictly speaking, the term cryptogenic syphilis can hardly be applied either to Jullien's or to all of Waelsch's cases,

for the point of entrance of the poison into the system was known in the majority of instances, though the initial lesion did not manifest itself at the seat of inoculation; these are rather cases of syphilis without chancre than of cryptogenic syphilis. But there is another class of case in which the victim of the disease is unaware of the occurrence of any breach of surface on the skin, or even of contact with anyone suffering from syphilis, and in which the method of entrance of the poison remains a mystery; to such cases the term cryptogenic syphilis may justly be applied. The author notes that the cases of cryptogenic syphilis, which came under his observation, were characterized by unusually severe sequelæ, and were usually unamenable to the ordinary methods of treatment. It is an axiom that the earlier the treatment of syphilis is commenced the better is the prognosis of the case, if efficiently and sufficiently treated; if the sore is capable of early detection and diagnosis, and especially if it admits of excision, the subsequent evolution of the disease is considerably modified. But in the class of case now under consideration the patients suffer from the disadvantage that an early diagnosis is impossible, and the treatment cannot be commenced until the symptoms are obvious, until the system is thoroughly impregnated with the poison. Induration of the dorsal lympathic of the penis and of the inguinal group of lymphatic glands is an indication that the poison has been introduced by means of sexual intercourse. In urethral chancre a urethral discharge may lead to the diagnosis of gonorrhea, and may be treated as such by injections and balsamic remedies, and the author encountered several such cases in which an obvious secondary sphilide had been attributed to the use of antigonorrheal remedies such as copaiba and cubebs.

7. The Bactericidal Action of the Cresols and Allied Bodies and the Best Means of Employing Them. E. A. Cooper.

1. Wertheim's Operation for Cancer of the Cervix Uteri.—J. D. Malcolm states that the most efficient factors favoring good results, immediate and remote, in cancer of the uterine cervix are an early diagnosis and a prompt operation. The tendency to irregular hemorrhages accompanying the disease favors an early diagnosis, and it is of the utmost urgency that the possible significance of irregular hemorrhages and the need for investigating their causes should be known as widely as possible among women. The results of early operations are very good, both as regards recovery from the operation and a permanent relief. In the later stages of the disease the immediate and the remote results are very bad, and the operation should not be recommended unless the death-rate can be kept at least moderately low. Wertheim's method of operating is a very great advance on any other.

5. The Appendicitis Dilemma and the Preoperative Diagnosis.—W. Ewart contrasts the situations presenting themselves with reference to appendicitis "of physical signs" and appendicitis "of symptoms." Physical signs are at a discount with the surgeon. Present when they are "superfluous" for his decision, they are generally "absent" in a majority of his cases where he would be the first to welcome them. That is the chief gravamen from the side of the patients; they might fairly object if they knew that their operation was being undertaken without any objective evidence. In the second and larger group we have no physical signs so far: the symptoms or our dread of them decide the operation. The weakness of this broad classification, convenient so far as it goes for the present discussion, is that it contains no reference to the gravity of the case. The most awkward of our facts is that some of the worst lesions must inevitably remain truly latent by reason of the occasional slightness of any inflammatory reaction. But, with that exception, taking the bulk of cases, the only "absolute latency" has been in reality that of any adequately efficient method of diagnosis. The author believes that it would be desirable to reduce Group 2, now almost all-absorbing, to its legitimate limits, which are much narrower than is generally suspected; and to assign to Group 1 its due proportion, which will probably be found to be increasingly considerable.

7. The Cresols and Allied Bodies.—E. A. Cooper recommends for disinfection of hands, instruments, pus, etc., the following preparations: Crude carbolic acid (cresols) emulsified with soft soap, and a crude mixture of tar acids from creosote oil, emulsified with castor-oil soap. The directions for preparing the former are as follows: Take equal weights of crude carbolic acid and soft soap; heat them together at 80° C. until all the soap is dissolved and filter the product. The preparation is a dark colored homogeneous fluid readily miscible with tap water, forming a slightly turbid liquid. The dilution recommended for hands and instruments is 2 per cent. The dilution recommended for disinfection of stools, pus, and other particulate organic matter, on the assumption that for one volume of stools, etc., at least two volumes of the diluted disinfectant be added is 3 per cent. This preparation is identical with the liquor creosoli saponatus, official in the German, Japanese, and Swedish Pharmacopœias, and with the Cresolum saponatum of the Belgic and Swiss Pharmacopœias. The "crude mixture of tar acids" contains cresols and their higher homologues, together with some carbolic acid, and is obtained by the extraction of cresote oil with soda and acidification of the extract. Take 50 parts by weight of this mixture of tar acids and 20 parts of castor oil (bleached and filtered oil of commerce), mix well and heat to 90° C., add a solution of 5 parts of potash in 5 parts of water, and heat and stir until a drop of the mixture gives a pink emulsion with tap water with no fatty scum. The product is a dark-colored fluid, miscible with water, giving a stable pink emulsion. The dilution recommended for hands and instruments is 1 per cent. The dilution recommended for disinfection of stools, pus, and other particulate organic matter, on the assumption that for one volume of stools, etc., at least two volumes of the diluted disinfectant be added is 1.5 per cent.

The Supposed Specific Biological Effects of Mineral Salts.—Schloss refers to the demonstrated facts of the necessity of mineral salts for the integrity of tissues and performance of functions. To show the rationale of their action is naturally a very difficult proposition, which can only be solved piecemeal if at all. Thus one may investigate the possible rôle of salts in water metabolism, on fluctuations in weight, on thermogenesis, etc., etc. These lines of research have been cultivated for some years past and many peculiar data have been obtained. If for example animals receive equimolecular amounts of calcium lactate, acetate and chloride respectively, the first is followed by gain in weight, the third by loss in weight, while in the second results are negative. Since the ration is the same for each salt, the inference is that the differences in result are due to the anions, which appear able to affect specifically the water metabolism. A study

of this subject at the bedside, however, tends to upset the ionic theory, for it shows that calcium chloride increases the water excretion of both skin and kidneys, while calcium lactate diminishes both, and calcium acetate diminishes the urine but increases the perspiration. Gain in weight as a result of ingesting a particular salt comes about through the fact that less urine is passed while there is no compensatory activity of the skin. There is thus retention of the salt with water retention and weight gain. The halogen sodium compounds all cause this water retention, as does also calcium lactate. The phenomena of salt fever and dropsical edema are likewise dependent on the same kind of retention.

The Tissue Sites of Reduction and Oxidation.—Golodetz and Unna, junior, refer to the recent demonstration by P. G. Unna that cell nuclei are pre-eminently oxidative. This was effected by color reactions supposed to be caused by the presence of an oxidase in the nuclear and absent in the cell protoplasm. The latter is believed to contain a reducing enzyme. In order to demonstrate the truth or error of these assumptions, the authors chose fowls' blood as best adapted for isolation of cell nuclei. Various means were used to free the nuclei from the cell protoplasm, including digestive fluids. The nuclei were then tested for the presence of both catalase and peroxidase. Numerous other cells were similarly investigated, and it was found that aside from nuclei in general, certain tissues, as cartilage, were also free from catalase, and that wherever one of these enzymes was found, the other was practically absent.

Aschoff's Doctrine of Cholelithiasis.—Hans Kehr discusses the effect of Aschoff's doctrine on the therapeutic indications in this affection. The pathologist in question asserts that gallstones have two quite different modes of origin, to wit, stagnation and infection, in the former case the stones being sterile, and formed by precipitation of cholesterin from the bile. Hence we have a very plain indication to prevent this stagnation by drainage or extirpation. The author has now performed nearly 1900 laparotomies for gallstones, during a period of 22 years. For the first decennium he was indebted to the studies of Courvoisier, Riedel and Naunyn for placing his indications. Since that time he has been similarly influenced by the pathologist Aschoff and the surgeons von Bergmann and Langenbach. He pays a warm tribute to the supreme and final authority of the pathologist above either the physician or the surgeon. While the two eminent surgeons mentioned with Aschoff fixed the operative indications in accordance with the latter's views, this was done on empirical grounds only. Thirty years elapsed before Aschoff gave the true rationale for the complete extirpation of the diseased bladder, which if allowed to remain would still be exposed to the dangers of stagnation.

Münchener medizinische Wochenschrift.

June 13, 1912.

Diagnosis of Pregnancy by the Optical Method and Dialysis Procedure.—Abderhalden announces that pregnancy has been diagnosticated by these tests, and the rationale underlying the operation of the latter should be of the greatest significance for other subjects, notably the nature of the gestation toxicoses. The blood changes which make the diagnosis possible are due to the entrance into the maternal circulation of chorionic cells. The blood of the mother reacts to the heterologous albumin by producing enzymes which tend to homologize the latter. The optical method was developed as follows: Blood plasma was mixed with a solution of cane sugar and placed in a polarizing apparatus, which is left in an incubator at 37° C. and readings taken from time to time. If the animal has previously been immunized to cane sugar the original dextrorotatory action becomes levorotatory from clearage of the cane sugar. The blood has formed a sugar splitting enzyme, and it is able to produce enzymes in the same manner when peptones, fats, etc., are substituted for sugar. By immunizing with placenta peptone, a similar clearage reaction is present in a pregnant woman. The dialysis test consists in dialyzing the blood against distilled water. If the animal was pregnant the dialysate gave the biuret reaction, otherwise not. The exact technique is not published in full and doubtless will not be submitted until the method has been more fully elaborated. The first practical application will be in the abattoirs, as despite precautions pregnant animals are often slaughtered.

Treatment of Sexual Impotence.—According to Lissmann progress in clinical medicine tends to cloud and complicate this subject. The urologist and neurologist each claim the latter as their own, so that it has become a borderline study, developing in two opposite directions to its own detriment. The author is a neurologist, but is favorably impressed with Cathelin's epidural injection treatment in which the erection and ejaculation centers in the cord are directly stimulated or irrigated. Cathelin, who used only indifferent fluids, ascribed the favorable result to a vertebral trauma. The author added yohimbin to the ordinary saline fluid injected and has used the method with marked success in a number of cases of prolonged impotence in otherwise healthy men, after having first satisfied himself that there was actual exhaustion of the erection center. Ordinarily psychic impotence could readily be excluded by the total absence of morning erections. The benefit derived persists for some weeks. The treatment seems to be contraindicated in precocious ejaculation cases. If a middle-aged man is able to copulate successfully once or twice a week, he should be satisfied, as no treatment can be expected to give the potency of youth. Yohimbin has proved to be of great value to the breeder and veterinarian, but its action in man when given by the mouth or even subcutaneously is likely to disappoint. Naturally in the author's method we cannot decide as to how much of the benefit is due to yohimbin, for the Cathelin injection alone has given good results, although inconstant. With the combination the author has thus far had but one actual failure.

Diabetes After Whooping Cough.—Von Starck writes a very brief monographic article on this subject. Diabetes in the child is essentially a more puzzling condition than in the adult, for few causal moments under our old notions of diabetes are then apparent. The more modern view would accuse a pancreatic lesion, and perhaps that only. Such lesion might result exceptionally after the acute infectious diseases and such sequences are reported now and then. For example, parotitis is known to inculpate the pancreas. In a number of cases on record the pertussis followed by diabetes the reporters have not been slow in accusing a pancreatic complication, but there appears to have been none in which a complete autopsy was made. The author's patient has been improving under treatment and the disease is arrested at least. If a pancreatitis is present the patient can hardly be pronounced cured.

Deutsche medizinische Wochenschrift.

June 6 and 13, 1912.

Treatment of Chronic Nephritis.—Von Romberg calls attention to the two trains of symptoms which characterize this affection. One consists of alterations in the urinary functions and the other of the systemic reactions to the renal lesion. The appearance in the urine of albumin, blood, cylinders and renal epithelia, however important it may be, does not furnish us with therapeutic indications nor does it enable us to measure the severity of the affection. Of more significance from this viewpoint is the total amount of water and sodium chloride eliminated. Oliguria implies that the renal blood vessels and especially

the glomeruli are seriously compromised. Polyuria signifies the converse and that the vessels are oversensitive to diuretic stimuli. The excertion of sodium chloride furnishes a measure of the integrity of the canaliculi. The phenomenon of uremia is now known to occur in kidneys which are able to excrete normally the water and chlorides, and the same is true in a less degree of the phenomenon of edema. Increase of blood pressure is not a phenomenon which furnishes therapeutic indications, but if cardiac weakness develops the reverse obtains. In renal insufficiency we should limit the ingesta, notably the fluids, nitrogen, and all condiments and drugs which may directly irritate the kidney. The salt must also be cut down as much as the patient can well tolerate. The patient, if he has been very active, must cut down his daily output of energy and give himself special rest periods. The day of the eliminative treatment appears to have passed in simple renal insufficiency. This applies to Turkish baths and mineral water cures, both of which are now regarded as urgently contraindicated. The same proscription even applies to the customary sojourn in warm climates. Whether in renal insufficiency the organs may be roused to greater activity without prejudice is a disputed question. This would be effected by drugs which dilate the renal arterioles, such as the xanthin synthetics. Digitalis is naturally confined to cases in which weak heart is a complication. Calomel is no longer used because of the possibility of setting up mercurial nephritis. Uremia is an affection to be treated directly of itself as a toxemia, not indirectly by influencing the renal function. For convulsions the patient should be bled freely and the future may accept lumbar puncture as a remedy. Sweats and purgation, the author has abandoned. The individual manifestations of uremia may be met symptomatically—dionin and codein for the asthma, laudanum for the nausea and vomiting, and bromides and veronal for the nervous excitation. Naturally the treatment of the renal insufficiency is maintained in the presence of uremia, just as in its absence.

Prophylaxis of Scarlet Fever.—Von Drigalski has devoted himself at Halle for nearly five years past to this line of effort and no report has as yet been published. Of the first rank of importance here is naturally the question of the relationship of desquamation to contagiousness. Over 1,100 school children have been followed up to determine this relationship, and in not a single case was there evidence of contagion after the return to school of the patients. When in mild cases the latter are free from scales by the twelfth or fourteenth day it is manifestly a hardship to isolate them for the full six weeks. Cases too mild for treatment have sometimes returned to school while desquamating, but no contagion appears to have resulted. Naturally they were sent home as soon as the peeling was observed. In the author's opinion no good can come from taking a greater degree of pains. Naturally, in home life the danger from exposure is much greater. The school physician should assume some responsibility in connection with late nephritis following scarlet fever.

Improvement in Bier's Technique for the Stagnation Treatment of Surgical Tuberculosis.—Bier has now added to his mechanical plan of treatment the internal administration of iodides in doses of about three grams daily, children in proportion. The great diffusibility of this salt must always be borne in mind in connection with its therapeutic efficacy. There can be no doubt that iodine has a specific action against tuberculosis, but this cannot always be made manifest, for example, whenever it is possible for the drug to leave the blood rapidly in the urine. When the drug is given to patients with crippled kidneys, a severe idiosyncrasy so called may develop. When artificial stagnation has been produced mechanically the focus of tuberculosis may be suddenly saturated with the iodides given internally or as the author states with iodized blood. The author reports three cases. He admits that the stagnation treatment alone might be responsible for setting up three distinct complications, to wit, pain and swelling with tendency to formation of cold abscesses, overgrowth of granulation tissue, and severe acute infection. The internal administration of iodides, he believes, will antagonize all of these complications. One of his patients was a young woman with tuberculosis of both feet, in one of which a resection was required. The other foot was injected with iodoform glycerin. The lesions, treated with immobilization became much worse. The details of treatment are not given, but the patient was presented at the clinic greatly improved, as were both the other patients.

The Blood State in Graves' Disease.—Lampé announces that in the light of modern research our knowledge of the constant blood finds of this affection is becoming more and more confirmed. The white blood picture shows a constant lymphocytosis. Other phenomena sometimes alleged, as leucopenia, eosinophilia, and mononucleosis are not characteristic. The lymphocytosis of Graves' disease is not dependent on the thyroid but the thymus. In all well-developed cases the thymus is coinvolved. Graves' disease is a dysthyroidism plus a dysthymism. There is no further characteristic morphological alteration, but there are chemical peculiarities comprising delayed coagulation and a lowering of the freezing point. Adrenalinemia and glycemia are frequently found—the former perhaps constantly.

Cohabitation Cystitis and Pyelitis.—Sippel describes what might be termed a new occupational disease—the ascending cystopyelitis of newly married women. The discovery was made very recently by Wildbolz, who stated that the condition supervenes promptly upon defloration, is always unilateral, and is caused by *Bacillus coli*. He proposed to term the condition defloration pyelitis. Sippel states that the existence of a nongonorrheal cystitis in newly married women has long been known. A coli infection of the female bladder occurs under various conditions. The ascent of the process to the renal pelvis, however, is not commonly seen and forms a characteristic of the alleged new disease. Sippel does not believe it depends in any way on defloration, *i.e.* on hymenal lacerations, but very likely occurs by preference in women with rigid perineum and narrow introitus, in whom the urethral orifice is directly exposed to injury by the penis. Coitus becomes painful and the patients even shrink from the digital exploration. Attempts at coitus doubtless are responsible for the accidental introduction of the bacilli in the urethra. Aside from infection it is very common for newly married women to complain of urinary disorders which are doubtless hastily set down as chiefly reflex in origin. In these cases there is always a suspicion of infection of some sort. In any case in which there is a recent history of dyspareunia there is also a possibility of an infection. The prevention of this affection belongs in the domain of the hygiene of marriage.

Pneumococcus Infections.—V. Hutinel states that pneumonia in the child is far from being a benign affection in all cases, and one should give a reserved prognosis until the child is well on toward recovery, since even after the fever is going down one may have the localization of the pneumococcus in some one or more of the other organs. Some of the serious lesions thus caused are endocarditis, pericarditis, purulent pleurisy, and peritonitis of a very grave and septic form. There may result purulent otitis, causing purulent meningitis or encephalitis. Herpes, purpura, and cutaneous gangrene occur in connection with the skin. Lumbar puncture clears up the diagnosis when the brain is affected.—*Le Bulletin Médical.*

Insurance Medicine.

Medical Section of the American Life Convention.—The annual meeting of this society will be held in Chicago on Tuesday, September 3, 1912, under the chairmanship of Dr. Ambrose Talbot of Kansas City, Mo. Papers will be read on "The Wassermann Reaction and Its Value in the Detection of Syphilis," by Dr. Amand Ravold of St. Louis; "The Appendix as an Influencing Factor," by Dr. C. M. Rosser of Dallas, Texas; "The Selecting and Training of the Medical Examiner," by Dr. E. A. Babler of St. Louis; "Methods of Uranalysis Applicable to Insurance Examination," by Dr. S. H. Baxter, Minneapolis; "Prognostic Significance of Albuminuria and Casts," by Dr. C. Naumann McCloud, St. Paul. The secretary of the Section is Dr. F. L. B. Jenney, medical director of the Federal Life, Chicago, Ill.

American Association of Medical Examiners.—At the annual meeting held at Atlantic City on June 3 and 4, 1912, the following officers were elected for the ensuing year: *President,* Dr. Frank W. Foxworthy, Majestic Life Assurance Company, Indianapolis, Ind.; *Vice-Presidents,* Dr. Charles Theodore Cutting, Empire Life Insurance Company, Seattle, Wash.; Dr. Paul Fitzgerald, Prudential Life Insurance Company, Newark, N. J.; Dr. James W. Guest, Commonwealth Life Insurance Company, Louisville, Ky., and Dr. A. T. Gaillard, Traveler's Insurance Company, Philadelphia, Pa.; *Secretary-Treasurer,* Dr. G. Strohbach, Cincinnati, Ohio. The next meeting will be held in Minneapolis in June, 1912, on the two days preceding the meeting of the American Medical Association.

The Relations of State and Private Insurance to Each Other.—Alfred Manes says that the question of limitation of State insurance and of private insurance to their respective fields is being widely discussed. It must be decided in the near future what can be properly expected from these two different forms of insurance, what persons should be considered fit for one form and not for the other, what character of protection should State insurance give, etc., etc. Some nations have already introduced various limitations to State insurance, thus Germany insures officials whose salaries range under 5000 marks. On the other hand, Austria has a pension law which does not consider the amount of salary of officials, all being eligible. The German workingmen's insurance has been gradually extended until it includes many more classes than those contemplated by Bismarck in the original design of State insurance.

The first question to decide is the proper field for State insurance as differentiated from the field of private insurance. It has been fairly well agreed that in three contingencies the State should provide proper protection, namely:

1. During a temporary interference with the working and earning powers of workingmen. Such interference may be due to

(*a*) Disease, provided for by sickness insurance.

(*b*) Accident, provided for by accident insurance.

(*c*) Pregnancy, provided for by motherhood insurance.

(*d*) Lack of work, provided for by insurance against loss of employment.

2. During a constant interference with earning capacity, which may be caused by

(*a*) Consequences of disease, provided for by insurance of invalids.

(*b*) Old age, provided for by old-age insurance.

3. In case of death, which may result in three kinds of claims:

(*a*) Funeral expenses.

(*b*) Support of the widow.

(*c*) Support of the children.

Manes thinks that it is a grave mistake to think that State insurance and private insurance necessarily compete with each other. The opposite is more true, for State insurance simply popularizes all insurance and urges certain classes of the population that enjoy such insurance to seek farther protection by going to the private insurance companies. State insurance can only provide the minimum amount of protection, and experience in Austria and Germany has shown that government officials enjoying such protection are among the most frequent applicants for private life insurance. Moreover, the establishment of State insurance has shown private insurance companies that they, too, may rightly strive for a certain portion of the work delegated to the State: the establishment of conservation departments, of sanatoria for tuberculous policyholders, of preventoria, etc., show how private life insurance interests are beginning to understand the social possibilities of their work.

There is one marked difference between State and private insurance. In the former, the aim is to extend protection to all individuals without caring how good or how bad risks they may be. Private insurance, on the other hand, considers only standard risks, for the most part, rating up any substandard individuals. Standard risks, therefore, get less for their outlay with the State, for they must bear the burden of the substandard death rate. Such risks obtained best returns, on the average, with private insurance interests. State insurance, however, is aimed at prevention of economic dependence and poverty, from whatever cause, and cannot, therefore, exclude any individuals or, indeed, rate any of them higher than others.

Very important questions are presented to lawgivers by the possible effect of State insurance upon employers and employees. It must not be forgotten that too much State interference may cause diminution in the investment of capital in any one country with consequent damage to that country's welfare. On the other hand, the effect of the feeling of security against need and poverty may be very good on a certain portion of the laboring class. It may, however, result in shiftless and unambitious work among a great many individuals who are not driven to do adequate work because of fear of poverty of old age.

There has been a great deal said in Germany about false claims for annuities and indemnities among the laboring classes since the introduction of State insurance, and much that has been said is, indeed, true. It must not be forgotten, however, that such behavior is common to all classes; witness the number of false claims and simulations that annually confront private insurance interests. The fact remains, however, that the insurance of workingmen against accident, has led to increase in the time of convalescence in such common accidents as fractures, for instance. Manes thinks that the present is the best time for careful scientific study of such social phenomena in order that experience may guide any changes or innovations in State or private insurance in the future.—*Zeitschrift für die gesammte Verischerungs-Wissenschaft,* May, 1912.

Book Reviews.

A Text-Book of Practical Gynecology. For Practitioners and Students. By D. Tod Gilliam, M.D., Emeritus Professor of Gynecology, Starling Medical College; Gynecologist to St. Anthony and St. Francis Hospitals; Consulting Gynecologist to Park View Sanitarium, Columbus, Ohio; Fellow of the American Association of Obstetricians and Gynecologists; Member of the American Medical Association, of the Ninth International Medical Congress, etc. Fourth Revised Edition. Illustrated with 352 Engravings, a Colored Frontispiece and 13 Full-Page Half-Tone Plates. Philadelphia: F. A. Davis Company, 1911.

The present edition is an endeavor to bring this well-known book up to date and in doing this a part of its contents has been supplemented by necessary additions, the most notable of which are contained in the chapters on abdominal and pelvic lesions other than gynecological. In this, as in previous editions, it has been the author's policy to present a plain, connected narrative of the subjects under discussion, rather than to follow strictly scientific methods in classification and arrangement. In the new chapter the writer presents a brief account of cesarean section and operations on the stomach, duodenum, liver, gall-bladder, pancreas, and intestines, which is believed to afford a general résumé of these subjects sufficient for the gynecologist. But if, as the author claims, the technique of cesarean section is as nearly allied to the domain of gynecology as to that of obstetrics, it appears illogical to discuss such an important subject in a single page of text. In fact, the very essential operation of vaginal cesarean is described in four and a half lines. The author's name is most closely associated with the ventral suspension operation of the uterus which he has devised and one looks for rather a more complete presentation of the subject than is contained in the chapter allotted to the discussion of the same. The operation has been found to be a very serviceable one in a large class of cases, but the description and particularly the accompanying illustrations, are characterized by a lamentable lack of detail for one who may be led to consult Dr. Gilliam's book on this procedure for information at first hand. It is to be hoped that in future editions of the book the author will present the detailed facts in a more complete form. On the other hand the description of injuries to the pelvic floor and their practical repair is deserving of commendation, as the author calls particular attention to the necessity of recognizing the true causes of the lesions in this region and bases his descriptions of the operative treatment on a thorough and proper knowledge of the same. An up-to-date work which submits technical descriptions of operative procedures should be furnished, moreover, with a more satisfactory set of illustrations than are here presented. Most of them are too small and too intricate to aid the understanding of the descriptive text, as for example, the various steps in the performance of an abdominal hysterectomy, an important operation which could be much more clearly expressed by a series of satisfactory illustrative diagrams than by many pages of descriptive matter. The book, moreover, is written in a style that is frequently characterized by effusions of language that seem somewhat out of place in a text-book intended, as the author states, for students and practitioners, and it is questionable if such a manner of presentation serves the real purpose of a serious work.

Handbuch der Speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarzt für Ohren, Nasen und Halskrankheiten in Kaiserslautern; Dr. H. Preysing, Prof. der Ohren-, Nasen-, Kehlkopf-Heilkunde, Ord. Mitglied der Akad. für prakt. Medizin zu Cöln a. Rh., und Dr. F. Blumenfeld, Spezialarzt für Nasen-, Hals- und Lungen-Krankheiten in Wiesbaden. 1. Bd., 2. Hälfte, Lief. 2, 3; preis, Mk. 9. 1. Bd., 2. Hälfte, Lief. 4, 5; preis Mk. 8.50. IV. Bd., Lief. 1, 2; preis Mk. 12. Würzburg: Verlag von Curt Kabitzsch, 1911, 1912.

The three parts of this monumental work on the special surgery of the ear and of the upper air passages, which parts have been issued since the last reviews of this work appeared in these columns, maintain the high standard both in the text and in the profusion of illustration which has been set in the former parts. The first of the installments now under review represents one of the most interesting chapers in modern surgery, namely, that of plastic and corrective surgery of the nose and ear, both very important from the cosmetic viewpoint. The subject of nasal and aural prothesis, or that of providing artificial noses and ears, is discussed ably by Professor Port of Heidelberg. The plastic surgery of the nose and ear is treated most comprehensively by Jacques Joseph of Berlin. To note the extent to which this field of surgery has been carried, it suffices only to enumerate the various deformities of the nose that may be corrected, with little or no visible scarring, by the masterly methods perfected in most cases by the author. These deformities are classified as follows. A. Hypertrophy of the nose (rhinomegaly): 1. Hypertrophy of the bony nose, either an abnormally convex profile or an abnormal breadth of the bony portion. 2. Hypertrophy of the cartilaginous nose: a. abnormal arching of the triangular cartilage; b. abnormal length of the nose due either to a hanging septum or to excessive length of the entire nose; c. various deformities of the wings of the nose; d. deformities of the tip of the nose. B. The crooked or oblique nose. C. Nasal defects. The technique of the operative procedures devised for the correction of these deformities is described in detail and with the aid of illustrations showing the condition both before and after operation. These operations are mostly performed by the intranasal route and constitute a veritable wonderland of cosmetic surgery. The surgery of deformities of the ear is similarly described in great detail. Albert E. Stein of Wiesbaden writes on the therapeutic employment of paraffin, and the plastic operations about the face are discussed by Professor Bockenheimer of Berlin. This subject is continued at greater length in the next installment. The various operations for harelip and cleft palate are elaborately detailed. The illustrations in this section are numerous and admirably supplement the text. The same installment contains the beginning of the article on the *x*-ray diagnosis of diseases of the nasal accessory sinuses, the hypophysis, the teeth, and the ears. The first and second parts of the fourth volume contain the following articles: The resection and extirpation of the larynx, pharynx and esophagus, by Professor Gluck and Dr. Soerensen, who also write on the surgery of the mandible and of the tongue, the ligation of the common carotid, and the surgery of the thyroid. In this synoptic review of the contents of the portions of this work just issued it is impossible to convey any adequate idea of the character of the text, and of the artistic illustrations. The book must be seen to be appreciated .

Manual of Operative Surgery. By John Fairbairn Binnie, A.M., C.M. (Aberdeen). Surgeon to the General Hospital, Kansas City, Mo.; Fellow of the American Surgical Association; Membre de la Société Internationale de Chirurgie. Fifth Edition, Revised and Enlarged. With 1365 Illustrations, a Number of Which are Printed in Colors. Price, $7.00. Philadelphia: P. Blakiston's Son & Co., 1911.

The present edition is a more elaborate exposition of the author's popular original work, which has now been incorporated in one volume instead of being issued in two volumes as previously. The book has been brought up to date, and presents the various known and accepted methods for doing all the operations included under general surgery. The book is extensively illstrated by selected pictures from reliable sources. The writer has wisely omitted from his book any consideration of gynecological procedures, for when these are included in general works of this kind the result is usually unsatisfactory.

Immunity. Methods of Diagnosis and Therapy and Their Practical Application. By Dr. Julius Citron, Assistant at the University Clinic of Berlin, II Medical Division. Translated from the German and edited by A. L. Garbat, M.D., Assistant Pathologist German Hospital, New York. Price $3.00 net. Philadelphia: P. Blakiston's Son & Co., 1912.

While it is probably true that the traditional "busy practitioner" will come in the future to rely more and more upon the laboratory worker for the technical part of immunity reactions, nevertheless the application of results both for diagnosis and treatment must always remain in the hands of the clinician. To make the best use of the information furnished by the immunologist the practitioner must keep himself informed of the progress made in that branch of science, and for that purpose this book is designed. The details of the various reactions used in the clinic for diagnostic, therapeutic or prophylactic purposes are taken up and in addition are included certain fundamental considerations of questions which still are largely theoretical but which at any moment may attain practical importance. The various methods are critically reviewed and the technical details are carefully described. While because of its brevity the volume will not be in demand by the immunologist, because of this very characteristic it is especially adapted for the use of the physician and the student. It should be highly recommended.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-seventh Annual Meeting, Held in Atlantic City, May 14 and 15, 1912.

(Special report to the MEDICAL RECORD.)

(Concluded from Vol. 81, No. 24, p. 1167.)

Wednesday, May 15—Second Day.

A Contribution to the Symptomatology and Early Diagnosis of Thrombophlebitis.—Dr. LEWIS A. CONNER of New York read this paper. He said that evidence had been presented to show that thrombophlebitis played a much more important part in the symptomatology of the latter weeks of typhoid fever than was commonly supposed. Phlebitis might, and usually did, exist in the small veins of the legs and feet long before the usual symptoms of phlebitis of the large veins appeared. Many of the cases of pleurisy and pneumonia occurring in the course of typhoid were embolic in origin, and these emboli were especially apt to be produced at the beginning of such a phlebitis, often many days before frank signs of the trouble were noticed. Evidence was presented to indicate further that the obscure "posttyphoid septic chills" and most of the irregular febrile movements of the later weeks of typhoid fever were manifestations of a latent phlebitis. The relation of the "tender toes" of typhoid to phlebitis was discussed and an explanation of that condition offered. Thrombophlebitis was a condition that was more common in cases of typhoid fever than was supposed, and it began earlier, usually on the tenth or the fifteenth day. The disease tended to run a latent course before the larger veins were involved. At the New York Hospital, between the years of 1898 and 1912 there were 1,540 cases. Among these there were 78 (5 plus per cent.) of frank thrombophlebitis; probable embolism without signs of thrombophlebitis, 26; and "tender toes" without signs of thrombophlebitis, 10. Among the cases reported, multiple chills occurred in 22 cases; occurring in those patients with evident phlebitis, 17 cases; chills occurring before any signs of phlebitis, 6 cases; chills occurring before and during phlebitis, 7 cases; cases without any signs of phlebitis, 5 cases; "tender toes," 22 cases; occurring in patients with evident phlebitis, 12 cases; "tender toes" before any evident phlebitis, 7 cases; "tender toes" after signs of phlebitis, 5 cases; "tender toes" without any signs of phlebitis, 10 cases; cases associated with unexplained fever, 7 cases; associated with symptoms of embolism, 1 case.

Dr. E. LIBMAN said that they had made a limited number of studies as to the value of transfusion in these cases, and thus far all he could say was that the transfusion strengthened the patient and gave him a longer time to fight, but he had hitherto seen no direct curative result. Dr. Libman said that the paper of Dr. Conner seemed to him an unusually valuable one. For some years back he had suspected that the sharp temperature rises and chills seen in cases of typhoid fever, particularly toward the latter part of their course, might be due to thrombosis; in such cases blood cultures were often negative. He asked Dr. Conner whether he had been able to determine by blood examination in cases of thrombosis in general whether they were purulent or not. He found that in some cases of nonsuppurative thrombosis that while the total leucocyte count and the polymorphonuclear count were as high at the onset as in the purulent cases, the polymorphonuclear count did not remain as high later in the course of the disease.

Dr. WILLIAM S. THAYER of Baltimore called attention to the many cases of thrombophlebitis that occurred in typhoid fever, and especially in the pulmonary vessel. In the cases he reported pulmonary embolism occurred before signs of phlebitis in 19 cases; during the active signs, in 10 cases. This was a total of 29 cases and 33 per cent. of all he had under observation. Phlebitis with pulmonary symptoms of doubtful nature, 8 cases; probable embolism without evident phlebitis, 26 cases; pulmonary disease not embolic, 25 cases. There were, in his opinion, three types of embolism which should be considered, the transient dry pleurisy, the pneumonia with small areas, and the extensive plastic pleurisy. Among the cases he reported were 12 with bloody sputum.

A Note on Fatal Cases of Postoperative Embolism.—Dr. LOUIS B. WILSON of Rochester, Minn., said that between the years 1889 and 1899 there had occurred no fatal cases resulting from embolism, and during this time there had been performed about 3,000 major operations. On September 13 the first death occurred, and without any change in operators, no change in the nurses, no change in the anesthetic, and no change in the treatment. Among the possible reasons for this might be that during the ten years the operative cases were drawn from private practice, cases selected by members of the staff, and they were operated upon earlier than the usual run of cases. Another reason might be that there had been an enormous increase in the number of patients operated upon for stomach, gall-bladder, and other disorders. In many of these cases it was interesting to note the high percentage in which cachexia was marked. While there had been performed over 1,300 breast operations there had not occurred a single case of embolism. Eleven of these patients died on the fourth day; 21 died before the eighth day. Out of 43 cases autopsy was allowed in 31, and in most it was found that the emboli originated in the heart chambers. One case reported was a male, forty-three years of age, with a clinical diagnosis of asthma, paralysis of the vocal cords, and a tentative diagnosis of aneurysm of the arch of the aorta. The specific gravity of the urine was 1,028. He complained of difficult breathing, night sweats, and a fear of impending death. There were a dilatation of the arch of the aorta, asphyxia, and symptoms that pointed to death, probably from pressure. This patient died at his office. The autopsy findings showed that the asphyxia was probably due to pressure of the aortic dilatation upon the trachea. Dr. Wilson reported another case of a woman, fifty-one years old, who came in with a diagnosis of carcinoma of the sigmoid. She had diarrhea, blood in her stools, and had lost weight. She suddenly died. Summary.—From September 30, 1889, to September 15, 1899, there had been 6,000 operations, and with no deaths from emboli. From September 13, 1899, to December 31, 1911, they had had 57,000 operations, and 47 deaths from emboli. There had been no change in the operation, in the anesthetists, in the nurses, in the surgical procedure, in the anesthetic, in the treatment of the convalescence. The probable reasons given were: (1) During the first ten years the patients were drawn from the surgeons' private practice. Forty-two of these patients had suffered for from 2 to 35 years from severe chronic debilitating diseases, 4 had strangulated hernia, and one appendicitis. All were extremely sick when operated upon. Fifteen had a very low hemoglobin percentage; 12 out of 15 had a delayed coagulation time. (2) Certain changes in the regions that were attacked surgically. There was no fatality following operations upon the breasts in 1,346 cases; no fatalities followed operations on the uterus (449 vaginal hysterectomies). There had occurred no case of fat embolism. Eleven patients died on or before the fourth day before sitting up; 32 patients died on or before the eighth day and after getting out of bed. The general policy was now to get these patients up and about as soon as possible. At autopsy there were found 36 cases of pulmonary embolism, 10 cases of cerebral embolism, and 1 case of coronary embolism, a total of 47 cases. There was a large percentage of cases in which the emboli apparently originated in the heart.

On Secretory Processes in the Kidney.—Dr. T. G. BRODIE of Toronto presented this communication. After an active diuresis the convoluted tubules were found to possess a wide lumen. Comparative measurements of the active and resting tubules proved that this effect was due to a forcible distention of the tubule by the watery secretion from the glomerular surface, for this secretion was driven down the tubule under a considerable pressure. In the process of secretion by the tubule a number of granules were discharged by the cells into the lumen, and these were contained within thin membranes which, as microchemical tests showed, contained fat. The contents of these little spherules were apparently concentrated solutions of waste products, for on reaching the lumen they rapidly swelled to spheres of considerable size. This was probably due to the passage of water osmotically from the dilute glomerular secretion through the wall of the membrane into the spheres, an osmotic exchange which continued until either the sphere burst, or its contents reached the same osmotic pressure as that of the glomerular fluid. A further examination of the behavior of these spherules under conditions in which the glomerular secretion was prevented, confirmed the explanation given above. The spherules then remained of small size. This condition was attained by experimenting upon animals in which the spinal cord was divided in the lower cervical region. Such experiments had also given a means by which it could be determined whether any given diuretic acted upon the secretory cells lining the convoluted tubules. Typical secretory granules were found in the lumen of the convoluted tubules after such diuretics as caffeine, urea, or

sodium sulphate. There was also evidence to indicate that the fatty envelopes of these granules were absorbed in the lower portion of the tubules.

Glomerular Lesions of Subacute Bacterial Endocarditis.—Dr. George Baehr of New York presented this paper, which was read by Dr. E. Libman. He said that the characteristic kidney lesions of subacute bacterial endocarditis were originally described by Loehlein in 1910. The description of the lesions as studied by him and later by the author was as follows: Usually a small part, sometimes a large part, or the whole of the glomerulus was involved, and in the capillaries usually in the affected part, one could under proper conditions find plugs of cocci. The epithelium of the part of the glomerulus involved first swelled up and then underwent necrosis. The epithelium of the visceral layer of Bowman's capsule over the involved part proliferated and there was some desquamation. The involved part then became adherent to the parietal layer of the capsule, and meanwhile organization of the affected area occurred, the resultant being a fibrous mass which became clothed by epithelium which grew over it, from the epithelium of the parietal layer of Bowman's capsule. When the whole glomerulus was involved there was found the outer part fibrous tissue; the central part might remain as a homogeneous mass. Occasionally a hyaline ball was produced. Twenty-five cases of infection of the endocardium by the endocarditis coccus were studied, and of these 23 showed the lesions in the kidneys. In the few subacute cases they have had due to other organisms and in cases of acute endocarditis due to the ordinary streptococcus, staphylococcus, and gonococcus, such lesions were never found. In 10 out of 11 cases which Dr. Libman believed to be instances of bacteria-free, healing or healed stages of subacute bacterial endocarditis, the lesions were found. In these cases all the lesions of the kidney were in the healed stage. The percentage of glomeruli involved in the cases varied from 2 to 75 per cent.; most of them had over 10 per cent. of the glomeruli involved. The number of early lesions, as compared with the number of healed lesions, varied in the different cases, this variation being due to different factors, chief among which was probably the period of duration of disease before death occurred. The lesions seemed to be less frequent in the cases which had become bacteria free.

On the Principles of Treatment in Nephritis.—Dr. Martin H. Fischer of Cincinnati read this paper. He said that all the changes that characterized nephritis were colloid-chemical in nature, and were due to a common cause, namely, to an abnormal production or accumulation of acid (and substances that acted like acid) in the kidney. To this were due the albuminuria, the morphological changes in the kidney, the associated formation of casts, and the changes in the quantitative output of water and dissolved substances by the kidney. All nephritides were parenchymatous nephritides and differed only in that the changes in some were general (parenchymatous nephritis), while in others they were local (chronic interstitial nephritis). The fact that healthy kidney tissue existed between the patches of parenchymatous nephritis in the latter cases accounted for the scarcity of urinary signs in the latter disease. The relief of nephritis depended upon a removal of as many as possible of the conditions that were responsible for the abnormal production or accumulation of acid in the kidney, and a direct combating of the acid condition and its effects upon the kidney. To this end there were indicated alkali to neutralize the acid, salts, including NaCl, to reduce the effects of the acid on the kidney, and water that this might be present in a "free" state for the urine.

Stenosis of the Duodeum: a Statistical Study with the Report of a New Case.—Dr. John M. Anders of Philadelphia read this paper. He said that congenital stenosis was not considered in this discussion. The acquired form was most probably more common than had been supposed by internists, and it invariably developed secondarily upon morbid processes either in the duodenum itself or adjacent organs. An interesting relationship existed between duodenal stenosis and such leading causative affections as duodenal ulcer and carcinoma, as well as disease of the head of the pancreas. A new case was here placed on record, since it embraced certain details of interest and diagnostic importance. The stenosis in this instance was due partly to the constricting cicatrix of an old ulcer and partly to the kinking occasioned by the adhesions. The subject was further considered in three aspects: (*a*) The incidence of the condition, including a collective investigation into the cases recorded in medical literature; (*b*) the etiological and pathological causes, and (*c*) the diagnosis. A totality of upward of 200 collected cases were presented in tabular form. No cases of duodenal disease, which were found recorded in the literature, in which any doubt of actual stenosis existed, and of which there were many, was embraced in the series. The accompanying table, which was largely self-explanatory, set forth the names of the reporters and the references, pathological causes, whether intra- or extra-duodenal, and also whether benign or malignant. Again the presence or absence of kinking was noted, and any points of unusual interest. The causal conditions were divisible into two groups—benign and malignant. About 20 per cent. of the aggregate number of cases were dependent on malignant diseases of the duodenum, pancreas, and other adjacent structures. Of the benign forms, the greater number were occasioned by duodenal ulcer. In 29 instances constriction of the duodenum was the result of compression by the root of the mesentery. Ochsner reported 15 cases in which spasm of the hypertrophied muscular layer of the duodenum operated as a cause of the condition. Among other factors in the production of duodenal stenosis of benign character were peritoneal adhesions and bands, gallstones (eight cases), cysts of the pancreas, kinking, hematoma of the pancreas, and ovarian cyst. A point of interest was that about 65 per cent. of the cases were of intraduodenal origin. The diagnosis of stenosis of the duodenum might be impossible, or practically free from difficulty, according to the seat of obstruction. For example, if the stenosis was located above the ampulla of Vater, it excited a symptom complex, which could not be distinguished from that of pyloric constriction. On the other hand, in the more usual chronic type of infrapapillary stenosis, a fairly characteristic grouping of features were presented, of which the chief were paroxysms of pain in most cases referable to the right epigastric region, occurring from three to five hours after the ingestion of food, vomiting, the vomitus containing both biliary and pancreatic secretions, but no fecal matter, acholic stools, constipation, and epigastric distention relieved by emesis. Dilatation of the stomach was present in the majority of instances, but not so constantly as in suprapapillary stenosis. Cases in which the obstruction was opposite to Vater's ampulla presented characteristic symptoms, which differed in certain particulars from those of infrapapillary stenosis. Stenosis of the jejunum could not be distinguished from infrapapillary constriction with any degree of certainty. Other diagnostic features were discussed.

A Clinical Study of a Thousand Cases of Ulcer of the Stomach and Duodenum.—Dr. Julius Friedenwald of Baltimore read this paper. He said that the thousand cases occurred in 12,598 patients affected with various gastric disturbances (7 per cent.). The largest proportion occurred between the twentieth and fiftieth years, and the greatest number between the twentieth and thirtieth years. There were 676 females and 324 males. As to occupation, 31 were cooks, 18 were workers in metal, 12 in porcelain, 8 were miners, 28 were tailors, 15 shoemakers, 19 blacksmiths; a definite history of trauma was elicited in 23 cases. Anemia was present in at least 65 per cent. of all cases. Of the entire number 774 were treated medically, 91 were operated on; 20 of the 91 operated upon had been first treated medically. Of the 774 cases treated medically 511 were given the rest cure treatment, while 263 were treated as ambulatory patients. Of the 511 treated by the rest cure 394 underwent the Leube treatment and 107 the Lenhartz, or a slight modification of the same. Of the 394 treated by the Leube cure 287 (or 72 per cent.) were cured, and 92 (or 23 per cent.) were not cured, and 15 died (4 per cent.). Of the 107 treated by the Lenhartz treatment 73 (or 68 per cent.) were cured, 29 (or 27 per cent.) were not cured, and 5 (or 5 per cent.) died. Of the 263 cases treated as ambulatory patients, 147 were treated with nitrate of silver, 106 with subnitrate of bismuth, and 10 by the olive oil method. Of the 147 treated with nitrate of silver 66 (or 45 per cent.) were cured, while 81 (or 55 per cent.) were not cured. Of the 106 treated with subnitrate of bismuth 56 (or 53 per cent.) were cured, and 50 (or 47 per cent.) were not cured. Of the 10 treated by the olive oil method 4 (or 40 per cent.) were cured and 6 (or 60 per cent.) were not cured. End results: Of the 287 cases treated by the Leube method and cured 77 could be followed for a period of five years or longer after treatment. Of these 58 (or 75 per cent.) remained permanently well, while 19 (or 25 per cent.) had relapses. Of the 73 treated by the Lenhartz method and cured 35 could be followed for a period of five years or longer after treatment. Of these 27 (or 78 per cent.) remained permanently well, while 8 (or 22 per cent.) had relapses. Of the 91 cases operated on 64 (or 71 per cent.) were

cured and 20 (or 22 per cent.) were not cured, and 7 (or 7 per cent.) died. Of these 10 had perforations, of which 6 (or 60 per cent.) recovered, and 4 (or 40 per cent.) died. End results: Of the 64 cases operated on and cured 45 could be followed for a period of 5 years or longer; of these 41 (or 91 per cent.) remained well, and 4 (or 9 per cent.) had relapses.

Defective Development from Arthritis in Early Life.—Dr. George Dock of St. Louis referred to the occasional references to impaired development following arthritis which were found in medical literature. Considering the relation of joint inflammations to the growing centers of adjacent bones it was remarkable not to find more actual examples. The case he reported seemed to illustrate the relations. Röntgenographs were shown.

Weight Curves in Typhoid Fever.—Dr. Warren Coleman of New York said that loss of weight had usually been considered as an essential symptom of typhoid fever. Previous investigations of the subject failed for the most part to state the amount of food taken by the patients, thus making comparisons of the results difficult. There was a general agreement, however, upon the following conclusions: (1) The majority of the patients lost weight. (2) The extent of the loss depended upon the severity of the infection and the duration of the disease. (3) The maximum loss was reached in the third week, more rarely in the second. (4) Complications increased the loss of weight. (5) The loss usually ceased with the return of the temperature to the normal, but might extend to the third week of convalescence. (6) The majority of the patients gained in weight during convalescence, sometimes rapidly. (7) The loss of weight was usually ascribed to (a) the fever, (b) the so-called toxic destruction of protein, and (c) to partial starvation. (8) The loss due to each of these causes might be reduced to a minimum, or prevented by a liberal diet containing an abundant supply of carbohydrates. (9) Dr. Coleman exhibited a number of charts showing the weight curves of patients on low and high caloric diets.

Antityphoid Inoculation: Three Years' Experience with Its Use in Training Schools for Nurses.—Dr. Lesley H. Spooner of Boston reported that this work, stimulated by the results of antityphoid inoculation in the British Army, aimed to establish an immunity among nurses and physicians in hospitals, who under the best conditions suffered a high morbidity from typhoid. Its success depended upon its safety and the ease with which it could be accomplished. These ends were secured by the use of a low virulence vaccine administered at frequent intervals in small doses. The results, from point of view of (1) blood changes and (2) incidence of the disease, seemed to justify the procedure. The use of the same prophylaxis during epidemics was safe, sane, and most desirable.

A Case of Meningococcus Endocarditis and Septicemia with Late Appearance of Meningitis.—Dr. F. G. Finley and Dr. J. L. Rhea of Montreal reported the case of a male, forty-seven years old, who was admitted to the hospital after being ill for three weeks with chilly sensations, sweats, and articular pains, palpitation, dyspnea, and precordial pain. The physical examination showed a moderate cardiac enlargement, an apical systolic murmur, and a hemorrhagic nephritis, a somewhat enlarged and tender liver and slight ascites. The temperature was slightly elevated and continued for two weeks with a maximum of 101.3° F., and usually under 101° F. He then became dull, had a rigor on two successive days, a copious hemorrhagic eruption on the skin with rigidity of the neck and arm, and pathological reflexes; there was a leucocytosis of 29,000 to 31,000. Coma set in with death in four days after the appearance of the symptoms of meningitis. The blood culture and lumbar puncture gave a pure culture of the meningococci. The autopsy showed malignant endocarditis of aortic and mitral valves, acute hemorrhagic nephritis, and purulent meningitis. Smears from the cardiac valves and meninges revealed great numbers of meningococci, and pure cultures of this organism were obtained from these structures. The chief interest in this case lay in the localization of the lesion on the endocardium and the late development, so far as clinical evidence went, of the meningitis.

Metabolism of Scurvy in an Adult.—Dr. Louis Bauman and Dr. C. P. Howard of Iowa City believed that conclusions could not be drawn from this, the first accurate study of metabolism in scurvy of the adult. Nevertheless, in their experience, loss of various food constituents through the feces was less when fruit juice was added to the diet. The total sulphur metabolism was abnormal throughout. Chlorine and sodium were retained during the fruit juice period, but excreted in excess of intake during the preliminary period. More potassium, calcium, and magnesium were retained during the fruit juice period.

Demonstrations of Lesions of Nitrogen Tetroxide Poisoning.—Dr. Francis Carter Wood of New York reported a case of poisoning due to nitrogen tetroxide, and also presented photographs showing the results of experimental work in connection with the study of the pathological lesions incident to the action of the gas. He stated that the chief lesion in the human case was a lobular pneumonia accompanied by extensive emphysema. The chief characteristic of the exudate was its large content of cells from the walls of the alveoli. Evidences of a reparative process were very abundant, many of the alveoli being covered with large epithelial cells. In some cases ingrowth of connective tissue in the bronchi and alveoli had occurred. There was an acute bronchitis with desquamation of the epithelium and also thrombosis of the smaller capillaries. Exactly similar changes could be induced in animals by inhalation of very small quantities of nitrogen tetroxide diluted with large volumes of air. The first lesion was an acute edema with hemorrhage in the alveoli of the lung. If the animal survived this condition it went into a stage of desquamative pneumonia with filling of the alveoli with exudate and cells derived from the lining walls. After four or five days reparative processes began and the lung could regain practically its normal condition if the etching of the tissue by the acid fumes had not been too extensive. He also cited a number of illustrative examples from the literature of the subject, some 250 cases having been reported with about sixty deaths.

Election of Officers.—*President*, Dr. Lewellys F. Barker of Baltimore; *Vice-President*, Dr. Simon Flexner of New York; *Secretary*, Dr. George M. Kober of Washington; *Recorder*, Dr. S. Solis-Cohen of Philadelphia; *Treasurer*, Dr. J. P. Crozer Griffith of Philadelphia; *Councillor*, A. McPhedran; *Representative on the Executive Committee of the Congress of American Physicians and Surgeons*, Dr. William S. Thayer of Baltimore; *Alternate Representative*, Dr. Theodore C. Janeway of New York.

CONNECTICUT STATE MEDICAL SOCIETY.

One Hundred and Twentieth Annual Meeting Held at New Haven, May 22 and 23, 1912.

The Nervous Manifestations of Pneumonia.—Dr. John C. Lynch of Bridgeport said that the nervous manifestations were encountered in almost every case of acute infectious pneumonia. These manifestations might be divided into two types: Those which occurred in association with the disease, and terminated with the crisis; and certain manifestations that occurred during or after the attack, and did not terminate with the crisis. Of the former, some might be due to the sudden perverted physiological condition that the organism underwent as the result of the abrupt onset of the disease; others might be due to the high temperature; while others, and possibly all of them, might be dependent upon the toxins. The toxins were many and various. Some might be developed in the invading organism, while others might be developed from the tissues of the body by the destructive action of the pneumococci upon them. Of the toxins thus produced, some might have an affinity for the heart; others, for the liver, kidneys, or the central nervous system. A certain relationship was observed between; and under certain conditions, one or the other might predominate and give rise to special pathological effects. The nervous manifestations included chill, depression, pain, and delirium. The author further remarked that cerebral pneumonia occurred most frequently in children and young adults: but that it might occur in the aged, and that in them it was always a serious condition. He also said that another nervous symptom was the development of herpes on or about the lips, which might be regarded as a favorable sign; and that where transient palsies had occurred, they were probably toxic. Dr. Lynch asserted that pneumonia might be followed by exhaustion psychosis.

Dr. Harold S. Arnold of New Haven asked if some of the symptoms, which were commonly ascribed to the action of the toxins upon the central nervous system in pneumonia, particularly in fatal cases, were not the actual invasion of the meninges by the pneumococcus, which invasion produced inflammatory reaction. He also wanted to know whether pnenmococcus meningitis was not more common than many observers thought. He said that the fact which Dr. Lynch had mentioned, and to which Liebermeister had recently called attention, namely, the frequency with which he had found suppurative inflammation

of the meninges at autopsies upon pneumonia patients, in whom, during life, no meningitic symptoms had been observed, was suggestive.

The Responsibility of the Insane.—Dr. HENRY S. NOBLE of Middletown observed that it was of more than passing interest to note the frequency with which insanity was pleaded as a defense for crime, and that this frequency rendered it a medicolegal study. He remarked that underlying the whole matter of irresponsibility for crime, by reason of insanity, was a misunderstanding between the legal and medical professions. The attitude of those who wished to vindicate the majesty of the law was that no insane person was responsible for his acts. He stated that there was an attitude somewhat in advance of that which for years had been maintained by the courts, which was shown in a recent charge of an eminent jurist, to the effect that the most reliable and efficient test of responsibility where insanity was pleaded as a defense would be the question of whether the crime charged was the product and direct result of the insanity alleged. That insanity implied certain immunity from punishment, he said all would agree; but that every alienist of wide experience recognized that there were degrees of responsibility associated with insanity, and that the majority of the insane should be held responsible for many of their misdeeds. Dr. Noble thought that every medical officer, in charge of an institution for the care of the insane recognized that many of his patients often committed misdemeanors deliberately and with malice aforethought; and although knowing right from wrong, and with full understanding of the nature, character, and even consequences of their misdeeds, they continued to transgress. He said that the insane were sometimes subjected to mild forms of punishment, according to the nature of their offenses; and he referred to the fact that Dr. Mercier had said that to those patients whom he allowed "pocket-money," the prospect of having it stopped had restrained them from practices of mischievousness, and other destructive habits. Although the principle had been loudly maintained that no insane person was responsible, and should therefore, never be punished, yet in actual practice it had been found that a large percentage were responsible; and that they acted from the same motives and were influenced by the same considerations as those who were supposed to be in full possession of their faculties. Dr. Noble further said that all would agree that some of the insane were wholly irresponsible, and were justly entitled to complete immunity for their misdeeds; but that it could not be denied that a very large number, to some extent at least, were responsible for their misconduct. He felt that an endeavor should be made to determine just what mental conditions should exonerate the insane offender from some or all punishment. It was his idea that the insane should be divided into two classes—those dominated by desire and those dominated by diseased judgment. He felt that the former constituted the vicious insane, and the latter the conscientious; one was responsible, the other, irresponsible. He thought that each case should be considered by itself and an endeavor made to decide whether the act complained of was the direct effect and consequences of disease or not. It would be a step in advance when graduated responsibility of the insane was recognized in law as it was in medicine, and penalties regulated in accordance with such principles.

Dr. WHITEFIELD N. THOMPSON of Hartford said that obedience to tradition, conservatism and a more or less general belief that a large percentage of offenders against the law were in some way abnormal, stood as stumbling blocks in the way of due consideration of the varying degrees of responsibility of those suffering from some mental disorder. That there seemed to be no valid argument against partial responsibility in certain classes of the insane, and in others mentally defective; but that the rub came in obtaining recognition of the fact when victims of such states came into conflict with the law. He remarked that gradual mental deterioration was marked by partial, though not full, loss of responsibility. He felt, as Dr. Noble had, that it was important to take into consideration the individual's normal tendency; and whether he had yielded to the dictates of desire, or had acted in good faith, in obedience to the directions of a diseased judgment.

Dr. JAMES M. KENISTON of Middletown observed that if doctors and lawyers could get together they might solve the whole problem in a common-sense, practical way. The lawyer should be taught that an insane man is a sick man—just as much as if he had diphtheria or cancer; and should be treated as such. Further, in criminal or civil suits, the doctor—the expert—should be allowed to examine the person undergoing trial, and then tell the jury exactly what he had found. Dr. Keniston was in favor of abolishing the word "insanity," just as had been done with the word "consumption." He felt that different forms of mental disease were now recognized; and that with every one of those there was some bodily affection, mind and body suffering together, though in different degrees. He said that the experienced doctor should, by virtue of his skill and experience, be the best man to decide that question; laws, customs, and precedents, notwithstanding.

Dr. NOBLE remarked that he wished to emphasize the point that insane persons were not necessarily irresponsible for the acts which they committed.

Experimental Nephritis and Its Clinical Significance.—Dr. MAX R. SMIRNOW of New Haven said that nephritis might be produced by a variety of substances that reached the kidneys for excretion. Substances like mercury, lead, bacteria, other heavy metals or their toxins, drugs, etc., had been used experimentally with success with parenchymatous nephritis, glomerulo-nephritis or interstitial nephritis. Many writers had suggested intestinal absorption as a possible etiological factor for nephritis, he said; and it had also been suggested that disturbed metabolism, particularly that derived from disturbances of liver function, might induce nephritis. Experiments showed that rabbit feces extract and rabbit bile produced in the rabbit both a parenchymatous and an intestinal nephritis, depending on the length of time the experiments were carried on. In those experiments, a secondary anemia was found to frequently accompany clinical manifestations. It was his belief that absolute proof of similar action of bile and other substances absorbed from the intestine in man was still wanting; but that its inference was justifiable from the experiments made.

Dr. GEORGE BLUMER of New Haven said that so far as clinical manifestations of autointoxication were concerned, he wished to enter a protest; that he had not been able to satisfy himself that there were any clinical manifestations of so-called autointoxication; and that the great weakness of experiments of that kind had been pointed out by Dr. Smirnow, when he attempted to produce kidney lesions by the interperitoneal injection into rabbits of an extract of rabbit feces. His idea was that even if you produced a lesion, you did not know by what it was caused; that is by what particular thing in the mixture it was produced; and in order to reach a conclusion it would be necessary to test each different constituent in the bile. Even though it were proved that there were certain substances in the intestinal canal that, under normal or pathological conditions, were capable of setting up nephritis experimentally, yet it would not have been proved that those conditions were applicable to the human being. Apparently the intestinal epithelium had a certain amount of selective action on the substances which it took up; and if there was a substance which passed through them without being absorbed, it was unlikely to cause nephritis.

Dr. CHAS. J. BARTLETT of New Haven said that aside from the rather rare cases in which the chronic condition had followed acute nephritis, the arteriosclerotic type of the disease, and the occasional cases in which a definite chronic poisoning, like lead, was the cause, it must be admitted that the etiology of chronic nephritis was doubtful. In adopting the method which had been outlined by Dr. Smirnow, his aim was to get a bacteria-free extract of the feces. He thought the injection of this extract into the peritoneal cavity of the animals experimented on might not give a condition entirely similar to that obtained in constipation; but that it had the advantage of definitely introducing into the animal, in solution, a quantity of material that had been obtained from another animal of the same species. The results were encouraging. A considerable percentage of the animals showed definite interstitial lesions of the kidneys. The most surprising result was the obtaining of equally marked lesions when bile alone was injected; although in that case the number of animals tested was small. He also said that so far they had worked chiefly with one kind of animal, rabbits; and their kidneys had seemed to be very susceptible to the injurious action of the various substances. It was Dr. Bartlett's idea that the results of such experiments as he had made, could not be directly transferred to a discussion of the disease as it occurred in man.

Dr. SMIRNOW later remarked that they had worked on some bile, but not on the bile of the rabbit, and they had found that it produced an acute change in the kidneys. He said that human bile and bile taken from cattle would not give rise to interstitial nephritis; but to an acute process. As to the absorbability of those substances, there were some experiments that would prove, as Dr. Bartlett had said, that they might be absorbed.

The Present Status of the Vaccine Treatment of Diseases of the Ear, Nose, and Throat.—Dr. Frederick N. Sperry of New Haven said that vaccines were available for the treatment of infections where antibodies were produced in insufficient quantities, and most available where comparatively small amounts of toxin were being absorbed, and consequently the formation of antibodies was likewise small. He said that the introduction of vaccine stimulated the general production of antibodies, and the production was usually in excess of the amount necessary to neutralize the vaccine. With excess of antibodies there would be an increase of the bactericidal power of the blood. In diseases of the ear, nose, and throat, he observed that the conditions were good for vaccine treatment, and that such troubles were usually a localized infection, often in an area of lowered resistance. It was stated that there was a minimum of toxin absorption, and a consequent insufficiency of antibodies. In such cases the whole body should be called upon to help manufacture a resistance. The author considered the reports of the use of vaccines unreasonably variable, more than could be accounted for by scepticism and enthusiasm. It seemed fair to assume that some fault in the technique was to blame for the lack of good results. The chief difference between the method of those who had failed to obtain good results and that of those who had succeeded was the longer intervals between treatments (such as a week or more, as compared with three days), and the using of stock vaccines as compared with autogenous. Dr. Sperry's cases numbered 17, and included a variety of conditions. While most of his cases showed marked improvement, yet he had a few instances of failures. He also said that tuberculin was a potent agent for the treatment of tuberculosis, inasmuch as it stirred the system to combat when judiciously administered. His idea was that while in vaccine there might be had an efficient helper, which at times might do the work of the chief, yet the best results were to be had by following out the regular lines of medical and surgical treatment, and using vaccine as an adjunct.

Dr. E. Terry Smith of Hartford said that during the past few years he had used vaccines in the treatment of a number of conditions and considered them of value, in those cases which had inflammatory conditions, in furunculosis, in some cases of actual otitis media, and in exanthematous diseases. He also felt that tuberculin might be given with brilliant results by a man who was thoroughly competent and appreciated all the attendant dangers.

Dr. Gegrge Blumer of New Haven said that when one considered the number of strains of gonococci in the different infections, it would not be hard to appreciate the necessity for using autogenous vaccines. He felt that the giving of vaccines was of little use, unless something was done locally to change the circulatory conditions.

Dr. Sperry thought that stock vaccines might be used with some value in cases of staphylococcous infection.

The Open Air Schools.—Dr. Henry M. Steele of New Haven was heartily in favor of open air schools, and mentioned the fact that they were attracting attention, not only in our country but in England and Germany as well. He said that there had been open air schools established at Hartford, and at South Manchester, and that he had been appointed by the Civic Federation of New Haven to establish such a school. He said he had done this by securing individual subscriptions with what assistance the Board of Education had given in the way of furnishing the teacher and the regular school equipment. The Management of the New Haven Orphan Asylum had furnished the morning and afternoon lunch. For clothing the children wore the same as those of the Orphan Asylum, except when in the tents, at which time they had been additionally protected by very warm, heavy outer-garments, and had sat in felt-lined canvas bags. He observed that the children had shown marked improvement in health from the first, and said that it was their hope that this small school might emphasize the fact that fresh air would not cause children to take cold; as those who had had colds when they came, soon lost them. He felt that the regular public school rooms should be more freely and constantly ventilated.

Dr. Henry F. Stoll of Hartford said that the open air school in that city was at the end of its third winter. In that school they had children from parents who had died of tuberculosis, and in addition those who were nervous or had bad headaches. He mentioned one case of chorea which they had had, and which was particularly severe. The child could hardly walk when she came to them, but when she left she had been perfectly cured. The cases of headache had been cured promptly. Dr. Stoll said that the Hartford school had taken no open cases of tuberculosis, because they felt it would have been unfair to the other children, who were so delicate, and who might become infected. He said that the roof to the tents should be made of wood; that the sides should be walled up about six feet and ought to have two feet of sand under the floor; and that the building should face the south. He remarked that the expense had been about fifteen cents a day per child; this had included the salary paid the cook, the food, and paper-napkins. He remarked that the discipline had been splendid, and that many boys who had been known as "bad boys" before entering the school had materially changed after being there a short time.

Dr. Thomas G. Sloan of South Manchester said that the school there had been running sixteen months; and that upon comparing his figures with those of Dr. Steele, he found that they had not done so badly as he had previously thought. He said that they had found an average gain of four pounds a child, and one thing that had been insisted on at the South Manchester school was that each child brush his teeth every day.

Treatment of Tumors of the Mammary Gland.—Dr. Philip W. Bill of Bridgeport declared that every growth of the breast in a woman over forty should be operated on; for even if harmless, no one could say how long it would remain so. He felt, however, that it was not always necessary to do the radical operation, but that it was better to operate on ten breasts that might never become any worse, than to allow one patient to die from the tumor's having become malignant. He said that in benign tumor the operation might be done in such a way as to cause but slight disfigurement; and he hoped that in this era of early operations there might be a diminution in the amount of tissue it had been necessary to remove.

Dr. George N. Bell of Hartford said that he felt there was no class of cases that carried so great a responsibility in their final decisions as neoplasms of the breast; he could not understand why men that would have been the first to advocate operation in abdominal conditions, would advise their patients to wait. He said they must know the large percentage of women over thirty-five years of age, that have died with cancer, and that of that number, 50 per cent. could have been successfully operated upon, if they had been taken in time.

Dr. D. Chester Brown of Danbury declared that eight out of every ten cases of cancer of the breast were positively malignant; and that all a man in general practice had to do was to call every case that came to him a malignant one, and he would be right nine cases out of ten. It seemed to him that it was a criminal act to cut into what might seem to be a benign growth, in order to make sure; and if good results were to be obtained, the entire gland and growth should be removed.

Dr. Daniel F. Sullivan of Hartford remarked that so far he had not known of the State of Connecticut's having made any appropriation for the investigation and cure of tumors; whereas it had appropriated almost a million of dollars for the investigation of tuberculosis. It was his opinion that the very extensive operation that had been employed by most surgeons in the past was being gradually receded from. For the last fifteen years he had had but few returns of the disease in cases where he had done radical operations; but he wondered whether the radical operation was not too much of a disfigurement for the patient, and felt that something should be done along that line for improvement.

Dr. Bill said that if it ever became possible to remove the breast before malignancy had become established, the chance of doing away with the mutilating operation would present itself.

Some Reminders on Fractures.—Dr. Augustin A. Crane of Waterbury recommended the use of the *x*-ray in fractures, for the benefit of the patient and the protection of the physician; and said that if only one exposure was made, it should be after reduction; and that it required more skill to interpret an *x*-ray plate than it did to make it. Without the use of the *x*-ray, it had been impossible to understand and diagnose accurately fractures of the carpus, metacarpus, tarsus, metatarsus, and the articular surfaces of the long bones. For general purposes, he considered plaster-of-Paris the best material for fixations, and thought it a pity that it was not more generally used. The author remarked that Lane's plates should be employed particularly in open fractures and non-unions, and that a powerful bone-clamp should be used to replace the fragments, retain them, and hold the plate; also that Lane's technique should be followed closely. It was his opinion that the poor results reported by American surgeons were due largely to their having failed to observe all the requirements.

Dr. Ansel G. Cook of Hartford said that he felt there was a tendency to rely too much on the *x*-ray, to the exclusion of other means of diagnosis, and that it should not be accepted as the sole means.

Dr. William H. Carmalt of New Haven remarked that it was very important to observe frequently the splints in case of fractures, as they got misplaced without either the physician or patient knowing it. As the *x*-ray was only a shadow, and not a picture, he advised careful judgment in interpreting it. He emphasized the idea that it was a very difficult matter to put a fracture in place and keep it there, unless one watched it all the time. He advised the use of plaster-of-Paris, and thought that it should include the whole limb. It was his idea that bone-sprains were fractures, nine times out of ten; and that what was supposed to be Colles' fracture of the radius was almost always a complicated fracture of something else besides. A sprain which was put up and treated as a fracture would get well much quicker than one put up and treated as a sprain. If the distal portion could not be got down, he said to bring the proximal portion up, and place the parts in apposition.

Dr. Patrick J. Cassidy of Norwich said that he considered Dr. Crane's paper an educational one. It was instructive, because it advocated the use of the *x*-ray diagnosis and the necessity of fixation, while acknowledging the difficulty of the latter. He remarked that in his part of the State they had suffered from a "natural bone-setter," who had in several cases produced impaired vitality, and even death to the patients, who had disregarded the advice of the regular practitioner and gone to him. He said he wished that Dr. Crane's paper might get into the hands of the laity in his county.

Dr. Ernest H. Arnold of New Haven advanced the opinion that the *x*-ray should not be used at first, but a diagnosis be made without its use and then verified by the *x*-ray. He said that he always used the *x*-ray in treating fractures and that its use had done away with the conception of green-stick fractures. Most of his cases had been those of complete fracture and he also used plaster-of-Paris for fixation and advocated splints being put over at least two joints.

Dr. D. Chester Brown of Danbury said if Rosse's statement was true, that every dislocation was a fracture-sprain, then it would be good treatment to bring back the fragment and fix it, as had been done in the case of Lane's plates. He stated that he had seen Rosse's original plates; they were small fractures, but that it was easy to handle a big bone, as the fragment was brought into apposition and fixed there with some metallic pin, after which you got a relaxed ligament and loose joint.

Dr. D. F. Sullivan of Hartford maintained that the wound could not be made too clean, and gave for his reason the many cases of tetanus which followed compound fractures. In that belief he differed with Dr. Murphy who has advised against any interference with nature doing her work, by too constant cleansing.

Dr. Crane said that he sympathized with Dr. Cassidy's difficulties in having fractures referred to a specialist, so called, and averred that if he had been practising in Norwich he would have put fractures up in reinforced concrete, instead of plaster-of-Paris, the first visit. He remarked that none of the fractures he had seen had enough body to get hold of with a pin or clasp; they could be retained by pressure and immobilization. He quoted a caution from Dr. Beck, of Chicago, which was as follows: "The surgical busy-body, with soap and drug, has killed more fracture patients than all the dirt carried into them at the time of the injury."

(To be continued.)

Suprarenal Insufficiency in Acute Infectious Diseases.—Castaigne describes a syndrome occurring in acute infectious diseases of various kinds which he considers to be due to insufficiency of the suprarenal capsules. It consists of asthenia, arterial hypotension, abdominal and renal pains, vomiting, and in some cases sudden death. In general this train of symptoms has been ascribed to myocarditis or to unexpected effects of the use of serum. It is now recognized as due to the absence of the internal secretion of the suprarenal capsules. This condition has been seen in diphtheria, scarlet fever, typhoid fever, and erysipelas. A typical case in an adult is described, in which during convalescence from diphtheria, the patient was threatened with death as the result of this train of symptoms. The pulse became slow and there was threatened syncope. These symptoms were relieved by the use of suprarenal extract.—*Le Bulletin Médical.*

Medicolegal Notes.

Testifying as to Cause of Condition.—A physician may testify that from facts stated in his opinion, in answer to a question whether or not an accident, such as a fall, could have caused the condition in which he found the person injured, whether such condition could or would result from such facts.—Galveston, etc., Ry. Co. v. Greenig, Texas Court of Civil Appeals, 142 S. W., 135.

Expert Qualification as to Effect of Blow.—In a prosecution for assault with intent to murder a regular practising physician was held to be qualified to testify as an expert upon a hypothetical question as to what would be the effect of a blow on the head with a given instrument, with which it was shown the assault was made.—Lacoume v. State, Texas Court of Criminal Appeals, 143 S. W., 626.

Chiropractitioner Does Not Require License in Arkansas.—The Kansas statute, sections 5241 and 5243 of Kirby's Digest, provides that every person practising medicine in any of its branches or performing any surgical operation within the State without complying with the provisions of the act shall be guilty of a misdemeanor, and that any person shall be regarded as practising medicine in any of its departments, within the meaning of the act who shall append "M.D" or "M.B." to his name; or repeatedly prescribe or direct for the use of any person or persons, any drug or medicine or other agency for the treatment, cure, or relief of any bodily injury, deformity, or disease. The Arkansas Supreme Court holds that the term "agency" in the act must be construed with reference to the terms of the statute preceding it, and therefore limited to the prescription of drugs and medicine. An indictment, therefore, for the unlawful practice of medicine by prescribing an agency commonly known as "chiropractics" without a license to practise medicine was held not to charge an offence within the definition of the "practice of medicine." The court relied upon the definition of "chiropractics" as a system of healing that treats disease by manipulation of the spinal column. Hart, J., dissented, on the ground that "other agency" is a very broad term, including the use of the hands. He pointed out that the practice of medicine in all its branches includes surgery, and surgery is practised by manual operation as well as by instrumental appliances.—State vs. Gallagher, Arkansas Supreme Court, 143 S. W. 98.

Insurance Company Bound by Acts of Its Medical Examiner.—An applicant for life insurance stated, in reply to a question in his medical examination, as to whether he had ever before applied and been rejected by any other company, that he had made such an application, but had not, as yet, heard the result. The medical examiner wrote in the space reserved for his answer the word "no." The applicant did not read the report when he signed it. It was held that the applicant was not bound by the answer, the medical examiner being the agent of the company and not of the applicant; the company was estopped by the action of its agent, which was the act of the company, to assert the falsity of the answer, as written, as a defence.—Supreme Lodge vs. Jones, Texas Court of Civil Appeals, 143 S. W. 247.

Physician May Testify, Though His Fees Depend Upon Result of Case.—In an accident case it was contended that the evidence of a physician as to the nature and probable effect of the plaintiff's injuries must be disregarded by the jury because it was shown that the physician looked to a recovery in the case for his fee. The contention was not sustained. The court said that, in the first place, it would be a serious and unwarrantable reflection upon the integrity of a physician to say as a matter of law that his testimony was warped or influenced by the fact that, unless a recovery was had, he would not be paid for his services in examining or treating the patient. In the second place, if such a rule obtained, it would have a tendency to deprive those in need of the services of skilled physicians of such services, or at least put them to the necessity of paying for such services as had been rendered before the physician could testify. It is competent, when a physician has testified as to the character, nature, and extent of an injury, to ask him the amount of his bill and whether or not it has been paid for the purpose of showing bias and affecting his credibility upon this point. But when a jury, with these facts before them, has returned a verdict for the plaintiff, evidently based, or at least in part, upon the opinion of such physician, the court would not be warranted in disregarding that evidence and setting aside the verdict.—Lack Malleable Iron Co. vs. Graham, Kentucky Court of Appeals, 143 S. W. 1016.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SCHMIDT'S JAHRBÜCHER DER IN UND AUSLÄNDISCHEN GESAMMTEN MEDIZIN. By H. DIPPE. Vol. 313. 1912—No. 3. 146 pages; paper. A. Marcus & E. Weber, Publishers. Bonn.

PROCEEDINGS OF THE FORTY-SECOND ANNUAL MEETING OF THE AMERICAN MEDICAL EDITORS' ASSOCIATION HELD IN LOS ANGELES, CALIFORNIA, JUNE TWENTY-SIXTH AND TWENTY-SEVENTH, NINETEEN HUNDRED AND ELEVEN. 99 pages; paper. Published by The Secretary, New York.

A MANUAL OF SURGICAL TREATMENT. By Sir W. WATSON CHEYNE, Bart., C.B., and F. F. BURGHARD, M.S., F.R.C.S. Vol. II—New Edition. 570 pages; illustrated; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

COMPENDIUM OF DISEASES OF THE SKIN. By L. DUNCAN BULKLEY, A.M., M.D. 5th Edition. 286 pages; cloth; price $2.00 net. Paul B. Hoeber, Publisher, New York.

THE OCULAR MUSCLES. By HOWARD F. HANSELL, A.M., M.D., and WENDELL REBER, M.D. 223 pages; illustrated; cloth; price $2.50 net. Second Edition. P. Blakiston's Son & Company, Publishers, Philadelphia.

INFANTILE PARALYSIS IN MASSACHUSETTS DURING 1910. 154 pages; paper. Published by Massachusetts State Board of Health.

ZWEI JAHRE SALVARSANTHERAPIE. By P. EHRLICH, F. KRAUS, A. V. WASSERMANN. 195 pages; paper; price 6.50 M. Georg Thieme, Publisher, Leipzig.

KLINIK FÜR PSYCHISCHE UND NERVÖSE KRANKHEITEN. By ROBERT SOMMER. Vol. VII, No. 1. 96 pages; illustrated; paper; price 3 M. Vol. 12. M. Carl Marhold, Publisher, Halle.

HYDROLOGIE ELÉMENTAIRE À L'USAGE DES MÉDECINES. By ALLYRE CHASSEVANT. 208 pages; illustrated; paper; price 4 Fr. Vigot Frères, Publishers, Paris.

THÉRAPEUTIQUE USUELLE DU PRATICIEN; TRAITEMENT DE LA TUBERCULOSE. By Albert Robin. Vol. 1, No. 3. 650 pages; paper; price 6 fr. Vigot Frères, Publishers, Paris. Paris.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Vol. XIV. 356 pages; illustrated; paper. The Rockefeller Institute for Medical Research, Publishers, New York.

THE TECHNIQUE AND RESULTS OF RADIUM-THERAPY IN MALIGNANT DISEASE. By M. DOMINICI, M.D., and A. A. WARDEN, M.D. 27 pages; illustrated; paper; price 75c. net. J. & A. Churchill, Publishers, London.

A MANUAL OF CLINICAL CHEMISTRY, MICROSCOPY AND BACTERIOLOGY. By Dr. M. KLOPSTOCK and Dr. A. KOWARSKY. 371 pages; illustrated with 43 Textual Figures and 16 Colored Plates; cloth; price $3.00. Rebman Company, Publishers, New York.

DISEASES OF THE EYE. By J. HERBERT PARSONS, D.Sc., M.B., B.S., F.R.C.S. Second Edition. 684 pages; illustrated; cloth; price $4.00 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

EIGHTEENTH ANNUAL REPORT OF THE MANAGERS AND OFFICERS OF THE CRAIG COLONY FOR EPILEPTICS AT SONYEA, LIVINGSTON COUNTY, N. Y. 259 pages; illustrated; paper.

ZEITSCHRIFT FÜR CHEMOTHERAPIE UND VERWANDTE GEBIETE. By FR. KEYSSER. First Year, No. 2. 294 pages; paper; price 40 M. for 12 copies. Georg Thieme, Publisher, Leipzig.

THE THIRTEENTH ANNUAL REPORT OF THE INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION. For the Period Beginning January 1, 1910; Ending September 30, 1911. 372 pages; cloth.

DAS SUBAQUALE INNENBAD. By Dr. ANTON BROSCH. 114 pages; illustrated; paper. Franz Deuticke, Publisher, Leipzig and Wien.

MILK AND THE PUBLIC HEALTH. By WILLIAM G. SAVAGE, B.Sc., M D. 459 pages; illustrated; cloth; price $3.25 net. The Macmillan Company, Publishers, New York.

FIFTH ANNUAL REPORT, NOVEMBER, 1911, HOSPITAL FOR DEFORMITIES AND JOINT DISEASES. 91 pages; illustrated; paper.

DER INFANTILISMUS, DIE ASTHENIE UND DEREN BEZIEHUNGEN ZUM NERVENSYSTEM. By Prof. Dr. PAUL MATHES. 188 pages; illustrated; paper; price 6 M. S. Karger, Publisher, Berlin.

Medical Items.

Postoperative Ileus.—Luigi Vaccari believes that the cause of postoperative ileus is not the presence of the drainage tube, but the presence of a septic focus and circulatory disturbances; the drainage tube, the fragments of silk ligatures, and the immobility of the intestine are only contributing factors. This complication is the expression of infection only. The true factors in causation are sepsis, foreign bodies, and disorders of circulation and nutrition of the tissues. As to the desirability of drainage, whenever there is any cause for hesitation as to its necessity, one should use drainage. Hemostasis should be complete and the bleeding vessels should be covered by peritoneum, and the duration of operation should be made as short as possible.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended June 28, 1912.

CHOLERA

Places	Date	Cases	Deaths
India: Bassein	Apr. 29–May 4	12	12
Bombay	May 12–18	73	61
June 19, still present.			
Calcutta	Apr. 29–May 4	..	84

INDICATIONS FOR OPERATIONS IN DISEASES OF THE DIGESTIVE TRACT.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE N. Y. POSTGRADUATE MEDICAL SCHOOL.

In selecting a topic for to-night's meeting I thought it would be timely to broach the subject of indications for surgery along the digestive tract, and the reason for this is not that I can tell you anything especially new, but because of late years a great many surgeons have operated in instances in which, at least according to the opinion of other surgeons and physicians, such operative intervention does not appear exactly right.

Another reason is that almost weekly, if not daily, I meet with patients who come to me after having undergone one or two operations with unsatisfactory result, practically complaining of the same conditions they previously had, and these are just the cases in which the operations had not been done, as it were, of necessity, but of choice. And the choice was not exactly right. Now, gentlemen, before I speak on the indications for surgical intervention, you will perhaps permit me to say a few words with regard to the reasons why these unnecessary operations have been done and what should not be done, and then I will go over to the real subject.

So far as I can see there are two points which play a great part in these so-called not absolutely necessary operations. One is that a great many surgeons maintain that, while it is good to make a diagnosis, it is not always necessary to do so. They say you should not lose time in trying to arrive at a good diagnosis. They open up the abdomen and say, make the diagnosis right there, and do what is necessary. Then there is a theory which has perhaps been taken up before it is ripe, that cancers develop upon the basis of ulcers, especially in the stomach. This has led also to the expression of a precancerous stage and to the opinion that the precancerous stage must be taken away before that cancer arrives. Accordingly ulcers of the stomach must be excised out of choice in order to prevent the occurrence of cancer.

I shall now take up the first point with regard to the diagnosis. I need not tell you that it is of importance in each case to arrive at a diagnosis, no matter whether the case is under the care of a surgeon or of a clinician. Everybody knows that before we start on treatment we want to have the diagnosis, that sometimes it is not so easy to establish a correct diagnosis, and that for quite a while, no matter how much science will advance there will be cases in which the diagnosis cannot be clearly made at once. Now, if it is necessary and important for the clinician (I speak of the clinician in contradistinction to the surgeon, although both of them are physicians, and there is really no difference between the two, except regarding treatment) in a medical case to make the diagnosis, it is, according to my opinion, much more so for the surgeon before he undertakes the operation. Take a physician who has not been able to make a diagnosis. He will be able to do something for his patient, arrange his diet, look after him, give him some wise rules of precaution. No harm will be done to that patient. He will watch him, study the patient from day to day. After a while he may arrive at the right diagnosis. The main thing is to have the wish and the desire to study the case and to follow up the patient and to watch him. Later on some symptoms may come which make it probable that such and such will be the case, and after a while the physician really arrives at the right diagnosis. Now we will take the surgeon—not much harm is done in waiting until something unusual occurs. But if we take a case in which an operative procedure should take place and the surgeon has not made a clear diagnosis and says, notwithstanding, "I will operate," I think that in a great many instances harm can be done to the patient. In some instances perhaps not, but in others decided harm will be done to the patient; he will undergo much suffering, lose a great deal of blood, and receive some scars and wounds that should not have been made. I have read lately two papers by renowned surgeons, saying that no time should be lost by methods of examination. They cut open and see. This is their principle. But even if the abdomen is open and the disease is there—I will not say that the disease lies perhaps in another apart which is not accessible—it is often overlooked, and even if it is not overlooked, a correct diagnosis by inspection cannot at all times be made with regard to affections which are exactly in the abdomen. But sometimes the disease lies somewhere else, not at all in the abdomen. I refer, for instance, to conditions as hemorrhage of the bowels. In such an instance there may be venectases and ulceration within the esophagus. I have had cases in which the hemorrhage was manifested only through melena, nothing else. Here a gastroenterostomy will be of little use. The diagnosis by opening the abdomen will not be made in some instances. So I think that the surgeons should be the first to try hard with the physicians to make the clinical diagnosis. I will not say that there are no exceptional cases in which an operation is justifiable without a correct diagnosis, but I have in mind a clear conception of what the operation can accomplish, and if we know something definite that can be found out, then it is a different thing.

The second point is that which regards the theory

*Read before the Newark Medical League on April 15, 1912, at Newark, N. J.

of the development of cancers from ulcers of the stomach. This theory was promulgated by Professor Hauser, I think, about thirty or thirty-five years ago. He is a pathologist living in Germany, and found, upon studying in a fraction of cases of cancer of the stomach that some of them developed upon the basis of an ulcer. But the figure was exceedingly small. When the clinicians took it up at that time and studied this question correctly in autopsies, especially Rosenheim, a clinician living in Berlin, they came to the conclusion that about one in fifteen cases of ulcer of the stomach really gives rise to the development of a cancer. Some, especially the pathologists, who have looked after the autopsies very thoroughly, found even a smaller figure, one in twenty, but no one who has some experience has found that this is a frequent occurrence; that is, that cancer frequently affects patients with ulcers. My own experience would also be one in twenty, and this coincidence is so small, cancer being such a frequent malady, that it is doubtful whether ulcer plays a part at all in the development of cancer.

The question is, how is it that here in this country, physicians have arrived at an entirely different conclusion? A great many nowadays say that half of the cancers of the stomach develop from ulcers. This does not tally at all with my own experience and that of a great many others, but how is it that such a theory could have been established? I think it will probably be found that there was a mixing up of these two affections, cancer and ulcer, by the circumstance that all cancers have a tendency to necrose and to form ulcers on their surface. This is a known fact, but some of the gentlemen who advance this theory, that cancers arise from ulcers, may have taken the ulcers which are found on top of these cancers as a result of the cancerous development and necrotizing, turned the fact around and said that cancer comes from ulcer. This question will have to be thoroughly studied by the pathologists, and I doubt not that in a few years they will arrive at the conclusion that ulcers as such do not give rise to the formation of cancers, that ulcers are an entirely different process, and that they do not constitute a precancerous stage. That theory of a precancerous stage has caused a great many operations which, according to my experience, have not been necessary. There is another reason why this theory cannot be sustained. It has been found that in some cases where the ulcers have been entirely excised, examined under the microscope, and found distinctly benign, still, as in two such cases of my own, cancer has developed later on in the course of half a year or a year; while in a great many cases where ulcers had not been excised, a simple gastroenterostomy having been performed at the operation, no cancer has developed. Professor Kuemmel[1] of the Hamburg Hospital has recently written a paper on his experience as a surgeon during the last ten years in that large hospital. He speaks of this condition and mentions two of these cases; one of excised ulcer in which cancer has developed later on, while in a great number of other cases of ulcers of the stomach that have not been excised, nothing has developed. This also speaks against the theory of ulcer constituting a precancerous stage. Every one of you has seen patients afflicted with ulcer of the stomach for years. They go on living and no cancers develop. In cancer, on the contrary, we find a short history of digestive symptoms lasting for half a year or so. Among fourteen or fifteen cases of ulcer of the stomach we find a case ultimately giving the signs of a cancerous growth.

There is one more point on which I will speak right now. It regards the early diagnosis in cancer of the stomach, and how to get at it. I fully agree with the surgeons that nowadays it is often impossible to arrive at a strict diagnosis, to say whether there is a cancer or not. Now the question is whether these patients should be operated upon in order that the surgeon may see, and to attack the cancer. This is one of the most difficult questions to answer. I must say that, while in a small fraction of cases such a procedure is justifiable, on the other hand, in the great majority of cases this is not indicated. Of course, the question is how to make the diagnosis, and we cannot make the diagnosis if there are not sufficient real signs that there is a development of the cancer. You can see that five or six patients will have to be cut open before you find one where that is really so. And that would not do. We have no right to open five or six individuals in order to find in one a beginning cancer, even if it should result in benefit to that fifth patient. The other four have received no benefit from it and we have done some harm, and we are not entitled to do so. I have said before that the diagnosis cannot be so easily made. If you open up an abdomen and feel the stomach with your hands and think there is no cancer you may be surprised three months later that there is a cancer. We cannot make these operations every three or four months. You see that principle would not work. If we are in doubt we should not cut open. We would have to do it over and over again. The patient is all right for a year, then he comes again; you think there is no cancer, and then the cancer develops.

But it is a different thing if we have sufficient reasons; if there are symptoms which indicate that there is a cancer. And that is just the difficulty of the problem, to select just these cases and to say: "Here we are justified in operating." I think that after a while surgeons will have to work in harmony with the clinicians in such instances. The clinician will have to study these cases, and the clinicians will be the first ones to recognize the conditions in which an operation is justifiable, and then we shall work in harmony and be able to do some good in a number of instances. The methods of diagnosis will be developed more and more, and in a great number of cases, if not in all cases, it will be possible to diagnose early cancer of the stomach.

Now we will go over to the indications for operative intervention. About thirteen years ago I read a paper[2] on a similar subject before the Medical Association of the State of New York, and there I made two statements which I think still hold good today: First, operations on the stomach for malignant diseases should be performed as early as possible as soon as the diagnosis is made, if it is feasible; second, in all benign affections of the digestive tract just the contrary principle should prevail: first all medical means and measures should be exhausted, and if they fail to produce relief and we know that surgery can accomplish something, then it is time for surgical intervention. I think that these two principles also hold good now.

[1]Prof. Kuemmel: *Deutsche medizinische Wochenschrift*, No. 10, 1912.

[2]Einhorn, Max: "A Brief Summary of the Indications for Operations on the Stomach," *Medical News*, November 25, 1899.

And now, if you will permit me, I will go over the indications for surgical intervention so far as I can see them. As to the indication for operation in malignant affections, everyone agrees that, so long as there is no specific remedy for cancer and as a cancerous growth can be checked wherever it is accessible to the knife, it should be removed as soon and as radically as possible. But as you have seen before, the diagnosis is not always made at a stage when a radical operation can be performed. It is not the surgeon's; it is not the physician's fault. Nowadays the diagnosis is further advanced, and in many instances a malignant disease of the digestive tract can be earlier recognized. But before a radical operation is performed we should ascertain whether there is no general infection, because it is no use to cut out a growth anywhere if there is a secondary metastasis in the liver, glands, and other organs. The operation would not contribute to lengthening the life of the patient, but if radical operations are not possible, then sometimes palliative operations are feasible and advisable. You all know that in case of cancer of the esophagus or of the cardia, if developed to such a degree that the patient loses in flesh, one can make a palliative operation for a gastric fistula in order to give the patient nourishment. In cancer of the pylorus or cancer of the stomach interfering with the motility, with a great deal of vomiting, a gastroenterostomy can be done, and this is also a palliative operation to prolong life. Such operations should be done when they are necessary, when the patients are in a condition to stand them. If a patient is very old, above seventy, and in a weak condition, I think these operations are not of much use. The patients often die quickly. We must judge by what a patient can stand, and see that he derives some benefit from the operation.

In speaking of these malignant affections I would like to say a few words which do not strictly belong to the subject of to-night, but you will pardon me for mentioning them. A number of physicians consider it necessary to tell a patient that he has a malignant disease, and I think that the reason for this is that they think the patient will agree more quickly to an operative intervention. According to my experience and my feelings, I must say that I do not consider it right in any case to tell a patient that he has a malignant disease or a fatal malady, no matter who the patient is. We physicians try to study nature in a great many ways and learn from it, and we usually find that what nature has arranged is for the best of the organism. Those laws that have been arranged by nature cannot be improved upon. Now nature has arranged that people, when they are sick, should rather have hope that they will still recover; and if they die they pass away not knowing what happens; they are not conscious of it. We must imitate this and try and help nature in overcoming the difficulty of the disease. Our main object in life is to remove suffering, if possible, remove sickness; but if we cannot do so, to give as much comfort to the patients as we can. This principle stands first. There is nothing to upset it. Now I certainly am not in favor of deceiving. The physician should be truthful, but on the other hand he should care for the welfare of the patients. We must tell the persons near them, but not the patients themselves. If we tell the patient he has a cancer we upset him, make him sicker than he is, bring suffering upon himself and the whole family, and when they see him grow weaker and complain, and they cannot give him any encouragement, a great deal of suffering is brought not only to the patient but to the entire environment by this mismanagement. Everything the physician has to do can be arranged without telling the patient that there is a fatal disease. If we know that an operation will be beneficial, we arrange it so that the family knows the exact truth, and the patient is told that a minor operation is necessary, not for a fatal disease but for something that can be overcome. We simply tell him that it is better for him that he should be operated upon. I so often see the great misfortune that such words have brought about, that I thought it well to speak about it.

Coming back again to the indications, I will now take the benign cases and the indications for operations in benign affections. Here we can subdivide the entire group into two large classes. One, in which we have to deal with acute conditions. I will first speak of one condition, also emergency cases, in which an operation is nowadays not done; that is, acute hemorrhage along the digestive tract. Up to about ten years ago surgeons and physicians were divided in opinion on this point. Physicians treated these cases medically; surgeons operated. Nowadays the consensus of opinion is that it is better to treat medically these acute hemorrhages which come on suddenly, and for the reason that the mortality in operative cases is very great. If I am not mistaken, some surgeons mention 50 per cent. mortality, some 40 per cent., others 60 per cent. It is, on the other hand, proven that the mortality in these cases of severe hemorrhages, if they are not much interfered with, is exceptionally small; if treated by rest, medical treatment, and abstention from food, the hemorrage, as a rule, stops after a while.

In my own large experience I think I have had only two deaths from hemorrhage. That is very little because I have seen many during my practice. The same Dr. Kuemmel whom I mentioned before and who has had a large experience—he mentions about one thousand operations—is of exactly the same opinion. He also collected the material of other people and arrived at the conclusion that these cases of hemorrhage should not be operated upon immediately. I am speaking now of these emergency cases. So it has been agreed that all these cases of acute severe hemorrhages should be treated medically.

Now, just the opposite is the case if we have to deal with perforations. Here everybody agrees that the surgeon should operate as early as possible, as soon as the diagnosis of perforation along the digestive tract, stomach, duodenum, or lower intestines is made. We know that these cases usually succumb and that the operation is the more beneficial the quicker it is done, because if you wait long, only twenty-four hours after the perforation, the outlook is already very bad. More than half of the patients die, while the earlier the operation the less is the mortality. The main thing is to think of that and make the diagnosis, and I think in most of these cases of perforation the diagnosis can be made, provided the physician thinks of the possibility of such an occurrence. So all cases of perforation should be operated upon at once. Now the case is very similar in affections of the gall-bladder, pancreas, and appendix. If there is a very severe process, an acute infection, perforation, or a process which leads to perforation, then

surgery should step in. The same holds good with acute intestinal obstruction, provided the diagnosis is made. Here the diagnosis is not so easily made as in real perforation. But if we have sufficient reason to assume that there is such a process present, then the operation is the best thing. Here there is harmony. All physicians and surgeons agree in these acute stages.

Going over to the affections of a chronic nature, these are the cases in which it is sometimes not so easy to mark out the lines where medical treatment and where surgical treatment is indicated. We shall begin again with ulcer of the stomach, chronic ulcer of the stomach. Most physicians think, and this is also my opinion, that ulcer as such should be treated medically, and I think that in a great many cases even cures can be established. Now, in which instances should we make an exception and say that an operation should be performed? In this regard I would make the following suggestions: Hemorrhages which have appeared not only once, but twice, or three times, endangering the life of the patient, due to ulcerations which can be shown not to be at the cardia, and not due to conditions in the esophagus or along the cardia—for these I usually recommend an operation. This operation is gastroenterostomy, provided the ulcer is situated near the pylorus or in the duodenum. Of course, with that operation, gastroenterostomy, you establish a new canal and take away much of the irritation to which the ulcerated surface is subjected by the food, but if the ulcerated area is situated in the cardia, a gastroenterostomy does not bring any change, and you cannot get in there, as a rule, by operations and remove the ulcer. So we have to wait and see what else we can do. But these prophylactic operations in order to prevent a recurrence of the hemorrhages are very beneficial. I have seen a number of such cases where life has been saved and made comfortable just by such a prophylactic operation. The patient feels entirely well. But if not operated upon, we know that in a year or two he may have another hemorrhage and die.

Now we come to another group of chronic conditions in the line of ulcer; that is, where the ulcer leads either to a stricture of the pylorus or to a severe spasm, so that the food cannot pass from the stomach. In former years we could not very well recognize these cases, we could not make a distinct differential diagnosis between a spasm and a benign stricture. Four years ago I would have ascribed a condition in which we found a great deal of food in the morning to a stricture of the pylorus, but I have learned since that a spasm due to an ulcer in the neighborhood leads to exactly the same state without there being anything like a stricture of the pylorus. Nowadays we can differentiate and can make such a diagnosis, and that is a very important point which has come out in recent years. The test which helps most in these cases is the one with the duodenal bucket. If size 23 French passes through the pylorus into the duodenum and the bucket is pulled out in the morning, you will find that that part of the thread which has been in the stomach is white, but the other part, which was in the duodenum, is stained yellow if the pylorus is permeable. Then you know we have been through the pylorus, and if food is still present in the morning you know it is a spasm, not a real stricture. That is one of the most important points of diagnosis. With regard to the cases in which there is stagnation of food in the morning, I formerly thought that in such patients—especially if no improvement could be accomplished by strict diet—an operation should be performed, a gastroenterostomy. But within recent years I have found that by stretching the pylorus, especially if there is no ulcer in the pylorus itself, you can accomplish results which are as good as those brought about by surgery, and I have also found that beginning strictures can be treated in a similar way by stretching. But if we have tried that method without success, it has been done without danger to the patient. Otherwise I would not do it at all. In no case have I seen bad results. But if we see that we cannot get through the pylorus, and the patients lose, then these cases should be operated upon. We should not wait until they are too weak, until they have become skeletons. This is a good plan: We should try to keep the patients in good condition, and if we see that the treatment fails and the diagnosis is correct, and we cannot accomplish anything by stretching, then surgery comes in and helps. We try to make a new opening between the stomach and intestines. That is the group in which there are benign obstructions.

If there is no obstruction and the stomach is empty in the fasting condition, and there is still an ulcer and such severe pains that the life of the patient becomes unbearable, due to that continuous suffering, we try milk diet and rest for the stomach. Then if everything fails, and we wait one or two months and still the same pains continue, then an operation should be performed. Here we cannot promise a definite cure, but we can tell the patient that we will try and operate; the suffering is so great that it justifies the operation. Possibly there is an adhesion. The plan of the operation cannot be decided upon beforehand, only when opening the abdomen can we see what is best to do. But we know what we are about; we operate here to relieve the suffering.

Now we get a little further down, to ulcer of the duodenum. Many physicians think that ulcer of the duodenum should be operated upon at once. I myself am not of that opinion. I think that ulcer of the duodenum offers as good a prognosis as ulcer of the stomach, provided it is treated in a rational way and is treated in time; that means, before complications have developed. I have seen a great number of these ulcers of the duodenum in which I have been able to make a distinct diagnosis, and I think most of them get along all right. The reason for the difference of opinion here is that ulcer of the duodenum gives rise to perforations more frequently than ulcers of the stomach. But, on the other hand, I do not think that an uncomplicated case of ulcer of the duodenum is apt to do that. Only in those cases where the ulcers have advanced very far, and have already led to some complicated symptoms, dilatation of the stomach with continuous hypersecretion, even if there is no ischochymia, always gastric juice in large quantities being present, and pains—these also are cases in which operation should be recommended.

We come now to the gall-bladder and to the chronic affections due to gallstones. Formerly gallstones were treated medically. There are a few selected cases in which operations have been recommended and are still recommended, but recently some surgeons have stated that any gallstones, as soon as the diagnosis is made, should be removed. It is true, a gallstone is a foreign body and does not belong there, and if you could take it out like

a coin from the pocket, it would be all right, but if you have to open up and know that there are patients who cannot stand the operation, you must consider whether it is worth while. I would give the following indications for removing gallstones. I think gallstones which do not molest the patient very much should not be taken out. I know Dr. Ill is of the same opinion. But if there are attacks of severe pains accompanied by fever, indicating some inflamed condition of the gall-bladder, and perhaps some beginning infection, these are cases which should be operated upon. If one or two attacks of a severe nature have taken place with fever, then, I say, an operation is indicated. I recently saw a patient with Dr. Ill, where we both agreed just on that account. There were several attacks with fever, no jaundice, and the patient felt pretty well, but we were of the opinion that an operation should be done in order to prevent a recurrence of these attacks. Now we certainly must leave it to the patients, we cannot force them, but where the attacks are mild, with not much fever or no fever at all, occurring at intervals of a year or two, I do not think that such cases are urgent, or that in every case an operation should be performed.

As to appendicitis—we are going a little further down—this is a condition in which operations in recent years are done much more frequently than formerly. I think correctly so, because if a patient has had one or two attacks, he is liable to have more. We know that some of these attacks may become quite serious, some may lead to perforation, so, on the whole, the operation, even in chronic cases, should be recommended. But we must be sure that there is something there. But this side of the question has also been overdone. A patient who has some disagreeable sensation on the right side, but has never had an attack, comes to the physician. The physician examines him, pressing hard there—the patient goes to another one. He has pains and is now suffering all the time, not so much from his own appendix as on account of fear and anxiety, and ultimately there is nothing left except to operate and take the appendix out. The appendix may be entirely sound, as is very often the case. Again, reflex conditions have been ascribed to the appendix, and there is no doubt that a diseased appendix can cause some reflex disturbance all over the stomach, the intestines, sometimes producing vomiting. But if this is overdone, if the patient complains of such nervous symptoms as nausea, belching, and you operate, and take the appendix out, I think that is a mistake. I know a number of such cases in which there was only a functional gastric disturbance present. The appendix was taken out, but the operation did not help. Every surgeon will know similar cases. That is the reason why we should be careful in making the right diagnosis. When we know that the appendix is really diseased, it should be taken out.

There have been a great many operations done for ptosis of one or the other of the abdominal organs, I think that in recent years these operations have become less frequent. We all know of movable kidneys. Years ago every movable kidney was attached and stitched up. Nowadays it is very rare that a kidney that is prolapsed is treated that way. The same holds good with ptosis of the other organs. I have never been in favor of stitching up these prolapsed organs. The reason for this is that ptosis as such does not give any trouble and the second reason is that if we find an organ prolapsed, kidney, liver, or stomach, it is not one organ alone, but a number of them; there is a weakness of the body. Some enteroptotic conditions are described as congenital. I myself think they can be acquired. Probably more than half the cases are acquired. We can prove that by treating the system, in a number of cases there is a return of the organs to the normal. The patient picks up, gains ten to fifteen pounds, the ptosis disappears. I have watched such cases and described them. If it were a congenital condition, there would not be any possibility of such a change by just putting on flesh. According to my opinion, all of these ptoses should not be operated upon. It is the same with the colon. The *x*-rays have been very helpful in making the diagnosis of these conditions, but, if every little deviation from the normal should be changed, I do not think much good would result. I do not deny it in some cases of enteroptosis complicated with other conditions requiring surgical aid.

The ptosis as such does not require surgical intervention, only some other complicating conditions. A patient with enteroptosis may have something else, a condition which requires operation, but the ptosis of such a prolapsed stomach never requires operative intervention.

I am very grateful to you for letting me speak so long, and I am very glad that surgeons and clinicians have in the last twenty years advanced the field of digestive diseases to such an extent that a great deal of benefit has been brought to the patient, either by medical treatment or by surgical intervention. I think that a great boon to humanity will result if the physicians and surgeons act together in harmony, and try to accomplish the best for the patient, first by medical means; but if this is not sufficient, and an operation seems to be right and good, then it should be performed.

THE IMMIGRATION OF THE TUBERCULOUS INTO THE UNITED STATES.

A PROBLEM FOR EVERY NATION.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In the early part of 1902, when the Treasury Department of the United States, upon the recommendation of the Surgeon-General of the Marine-Hospital Service, decided to classify pulmonary tuberculosis with dangerous contagious diseases, I submitted the following resolutions to the New York Academy of Medicine:

Whereas, The Treasury Department of the United States, upon recommendation of the Surgeon-General of the Marine-Hospital Service, has recently decided to classify pulmonary tuberculosis with dangerous contagious diseases, be it

Resolved, That the New York Academy of Medicine deeply deplores this decison, which is not based either on clinical experience or on scientific experiments.

*Read before the American Academy of Medicine as a part of the symposium, "The Medical Problem of Immigration," at the annual meeting in Atlantic City, June 1, 1912. The paper was intended to be delivered before the Tuberculosis Congress in Rome, April, 1912. Owing to the inability of the author to be present, it was read only by title, but will appear in the transactions of the congress.

Resolved, That the Academy considers the exclusion of non-pauper tuberculous immigrants and consumptive aliens visiting our shores, unwise, inhumane, and contrary to the dictates of justice. Be it further

Resolved, That while the Academy is convinced of the communicabilty of tuberculosis and urges all possible precautions against the spread of the disease occasioned by sputum and tuberculous food, the Academy is opposed to all measures by which needless hardship is imposed upon the consumptive individual, his family, and his physician.

These resolutions were seconded by my beloved and much regretted teacher, the late Prof. Edward G. Janeway, and unanimously adopted at the Academy's regular meeting on February 6, 1902. Copies were sent to the Treasury Department, to the Surgeon-General of the Marine-Hospital Service, and to the medical press. A number of other medical societies passed similar resolutions.

The attitude which I expressed in these resolutions ten years ago toward the immigration of the tuberculous into the United States, I still maintain. I am to-day as strongly opposed as ever to allowing foreign governments to unload their poor and dependent consumptives on these shores. But I am also to-day as then convinced of the injustice, the inhumanity, yes, even the cruelty, of not admitting a well-to-do patient no matter in what stage of the disease, whether he comes as a mere visitor, with the desire to enter a sanatorium, or with the view of settling in some of our salubrious climates.

What would the United States government say if a well-to-do American citizen, whom his physicians had sent to Davos Platz, the Riviera, or the Black Forest, for the purpose of regaining his health, should be returned by the Swiss, French, or German government as an undesirable alien? That none of these governments have retaliated is a wonder. Recently a wealthy Englishman was detained on Ellis Island because of tuberculosis and it required considerable diplomatic cabling between London and Washington to have this refined, cultured, and well-to-do gentleman released and permitted to visit his friends in this country.

I mention this case merely to show you the unfairness of the Treasury Department's decison regarding tuberculosis. This decision is not only unfair but thoroughly unscientific; there is no basis for classing tuberculosis among the dangerous contagious diseases, such as smallpox, for example.

What modern sanitarian, philanthropist, or general practitioner would dare to make such a classification! Phthisiophobia, that is to say the exaggerated fear of the presence of a consumptive, has never received such an impetus as it secured from the Surgeon-General's recommendation. The word "contagion" comes from the Latin *contingere*, to touch, and surely, to the best knowledge of clinicians and experimenters, the mere touch of the consumptive has never yet given rise to tuberculosis in another.

It is possible that among my hearers there may be some one who has read the statement recently made by Poncet of Paris to the effect that the perspiration of the consumptive, that is to say the liquid matter secreted by the sweat glands, contains the tubercle bacilli. Thus far it has been impossible even to find the tubercle bacilli in the circulatory system, and Rosenberger's experiments, tending to show that bacilli can be found in the circulating blood of the tuberculous could not be corroborated by our most careful bacteriologists. The same must be said of Poncet's experiments. There is thus far no absolute bacteriological or clinical evidence of the presence of bacilli in the perspiration of phthisical patients. But even granting that Poncet's statement should be true, an infection from the cutaneous surface of the tuberculous patient by the mere touch is somewhat difficult to conceive of. A considerable quantity of the perspired fluid would have to find entrance into the digestive tract or enter the system by the inoculation process. The inoculation method could only be conceivable in the case that the supposedly infectious perspiration came in contact with an open wound. However, as everybody knows, the ordinary hygiene of the skin and the proper disposal of the soiled personal and bed linen of the patient would suffice to do away with even this possible source of infection. Such statements as that of Poncet, which after its announcement in Paris was cabled to our daily papers and printed broadcast, have invariably the unfortunate tendency to increase the, alas, already so widespread phthisiophobia. The lot of the average consumptive is hard enough as it is without increasing the unjustified prejudice against him.

We are preaching every day that to associate with a careful, clean, and conscientious consumptive is perfectly safe; that it requires prolonged exposure, absolute inhalation, ingestion, or inoculation of tubercle bacilli in order to produce the disease. Surely, no one can deny that the New York Health Department, under the leadership of Dr. Hermann M. Biggs, has done most efficacious work in the municipal control of tuberculosis. Yet, from the very beginning of our antituberculosis crusade, tuberculosis has been classed with communicable and not with contagious diseases.

In defending a more scientific and less oppressive attitude toward the tuberculous, poor or rich, as stated in the resolutions above referred to, I nevertheless maintain that it is absolutely just for any government to refuse to be burdened with the tuberculous poor of another country. Instead of returning the tuberculous immigrant we should prevent him from coming and so save him hardships and disappointments. Although a large number of tuberculous immigrants are returned, very many of them pass unnoticed. It is no reflection on the ability of the medical men at Ellis Island when I say they do not by any means detect all the tuberculous invalids, and that they diagnose only those who show very strong outward signs of tuberculosis. How should the men stationed at Ellis Island be able to detect at a glance a tuberculous invalid in a first or second stage, when it often takes an expert a half or three-quarters of an hour before he can arrive at a definite conclusion, and that after a careful examination in the quiet of his office?

The examining physicians on Ellis Island, because there are only a small number of them, can devote but very few minutes to each of the thousands of immigrants which pass before them weekly for inspection. The excellent appearance of some tuberculous immigrants, because of a ten days' voyage, invigorating sea air, good food and rest, has been to my mind in many instances the reason of the non-discovery of invalids in quite advanced stages. When they have been admitted to this country, a few weeks of hard work in the ditches or in the sweatshops, with nights spent in overcrowded tenements or unclean or crowded lodging houses,

usually suffice to bring about an exacerbation of the disease. The strain, the struggle for life, the new environments, the unaccustomed food, and perhaps also some nostalgia and disappointment, likewise help to turn, in a very short time, an incipient case into an invalid with open tuberculosis, and thus a new center of infection is formed. All this accounts for the great prevalence of tuberculosis among the laboring classes who have come to us from foreign shores only relatively recently. A goodly number of them return to their native land, particularly the Italians, when they realize that their disease does not permit them to struggle as they must if they wish to remain here. I have been told that there are villages in Italy where tuberculosis has become most prevalent because of the return of those emgirants and because their methods of life result in infection of others.

Some return voluntarily to their native homes, but you perhaps are not aware that we have a deportation law* which, as a good American, I am sorry to admit, seems unnecessarily harsh and unjustified, founded as it is on an unscientific basis. It is to the effect that any immigrant who has become a public charge in a hospital or other institution and is found to be tuberculous, can be deported even after a residence of three years if in the opinion of the examining physician he had contracted the disease prior to his landing on these shores. During the year of 1911, about 1,500 of such tuberculous aliens were referred to the State Board of Charities for deportation. On the strength of this law the deportation is done at State expense.

With all due respect to the framers of this law, I believe it absolutely imposible for the most skilled diagnostician, upon examination of a tuberculous chest, to state the duration of the disease with even approximate certainty. A declaration that an individual had tuberculosis for a definite period of time, based on a physical examination or even on the history given by the patient, must necessarily be guesswork. I know of a case of deportation which was declared legal upon the statement of a young physican to whom a tuberculous patient had admitted that he remembered having had a cough a little less than three years ago, prior to his coming to this country.

How many thousands of us have a latent tuberculosis which has never been discovered and which may never cause us any trouble if we continue to live carefully and hygienically! Should we, however, be submitted suddenly to a life of hard physical struggle, be transported into unhygienic environments, be underfed and badly housed, the development of the tuberculous trouble would be almost certain to take place, and in a much shorter time than three years. One must have witnessed such a deportation in order to comprehend its meaning, particularly when one is not at all certain that the case might not be one which developed right here because of hard work and privation.

And now, to the most important question of all: What can be done to prevent tuberculous invalids, likely to become a burden to the community, from entering the United States, only, perhaps, to be deported after a sojourn of one, two, or three years? Tuberculosis must be considered a world problem, a problem for every civilized nation. Let European governments understand that they must take care of their own tuberculous people as we take care of ours, and that in the end, by united efforts, it may be possible to conquer the white plague in all countries.

Every prospective emigrant should be examined to ascertain his freedom from tuberculosis by two competent medical men, one appointed by his home government and one by the steamship company which is to transport him to this country. A certificate showing freedom from tuberculosis, signed by these two medical men, should be in the possession of every emigrant wishing to come to these shores. An individual discovered to be afflicted with this disease should be returned to the care of the authorities of the city or village from which he came with the diagnosis and recommendation for treatment. Exceptions can and should be made in the case of an individual with ample means who is simply visiting, or seeking to recuperate his health by a change of climate, or desirous to enter an American sanatorium for treatment. To avoid misuse or fraudulent use of the physician's certificate, a photograph should be taken at the time of the examination in the home port, and attached to the certificate. Or, since a photograph could be removed and another one substituted on the certificate, I even go so far as to suggest that it would be well to have the finger print taken for identification. This is the most accurate and scientific method known for such purposes.

The laws relating to deportation should be changed to the effect that if the holder of any such certificate, or any immigrant develops tuberculosis within six months to one year from the date of his arrival here and becomes a charge to the community, he shall be deported to the port whence he came. The expenses for this deportation should be borne by the steamship company who brought the immigrant to our shores, and not by the State Board of Charities. Whether, to avoid possible mistakes in diagnosis, European governments, in cooperation with the steamship companies, should desire to keep doubtful cases under observation a few weeks or increase the examining boards by one or two more experienced diagnosticians, is a matter for the foreign governments to decide. There is no question but that the more careful these examinations are at foreign ports, the fewer the cases of deportation that will ensue.

The suggestion has been made that physicians of the Public Health and Marine-Hospital Service be stationed at the important points of departure in Europe so that each emigrant can be thoroughly examined, and those entitled to a clean bill of health be allowed to take passage. I question whether the international law would sanction such procedure. Secondly, there are too many minor points from which emigrants could take passage and escape the United States Government physician's examination. Of greater value would it be for foreign governments and steamship companies to make it known that if a man expects to stay in the United States he must not become a public charge; that he must be physically, morally, and mentally sound. With such publicity and the additional examination in the manner above outlined, the United States Government will be less burdened with the care of tuberculous aliens who, uncared for, are a constant menace to the community.

An interesting suggestion in relation to this subject was made at the recent International Tuberculosis Congress in Rome by Dr. Antonio Stella of New York. It was to the effect that every emigrant should be insured against tuberculosis, the

*Immigration Act of February 20, 1907.

cost of insurance to be added to the price of the steamship ticket, the policy entitling the bearer to return transportation and free treatment in a sanatorium, in the event of his contracting tuberculosis within a specified time. This suggestion was presented in the form of a resolution, which was unanimously adopted, but whether or not it results in any immediate or definite action, no country should continue to have uncared for tuberculous patients.

For the uncared for, the untrained, and untreated tuberculous are sure to propagate the disease among their kin and neighbors, and procreate a tuberculously predisposed race. The efforts of the medical profession and authorities in some of our States are in the right direction when they enact and enforce laws which forbid the consumptive from contracting marriage and when they declare that no tuberculous patient who is careless either knowingly or unknowingly, or is unable to take care of himself, should be allowed at liberty. It would be well for some of the foreign governments to establish similar laws and regulations. I go so far even as to recommend sterilization (vasectomy for the male and ligation of the Fallopian tubes for the female) if these individuals insist upon marrying while ill with a directly or indirectly transmissible disease such as tuberculosis. I believe in using the most humane means possible in all our efforts to suppress tuberculosis, but we should enforce them not merely in self-defense but in the interest of foreign governments themselves. I plead that they should take care of their tuberculous poor, educate, train, and treat them and heal those who can be healed. The hopelessly ill should be segregated to prevent them from infecting others and from procreating. This should be not merely an American or a national, but the international policy of every civilized nation. If any government will cure its curable patients and make of them strong, vigorous, self-supporting citizens, as we have been fortunate enough to do with many of our tuberculous invalids, then will we welcome these sane and sound people to our shores and try to make good Americans of them.

16 West Ninety-fifth Street.

ANESTHESIA IN SUBMUCOUS RESECTION OF THE SEPTUM NASI.

By JOHN ALLAN, M.D., B.Ch., D.P.H.,

LIVERPOOL, ENGLAND.

Within recent years the operation of submucous resection of the nasal septum has been widely practised for a variety of conditions. In discussing the question of operation not the least important point is the consideration of what form of anesthesia should be employed. The operation may be done under local anesthesia, or combined local and general anesthesia may be used. The exhibition of a general anesthesia only is seldom practised. At the outset I may say that I consider that the great majority of cases can be operated on under local anesthesia. Of various methods of inducing local anesthesia three may be mentioned: (1) Packing the nasal fossæ with gauze which has been soaked in a solution of the anesthetic; (2) injection under the mucous membrane or mucoperiosteum covering the septum nasi of a weak solution of the anesthetic; and (3) Freer's method.

The first is the method I invariably employ, and up to the present it has given me entire satisfaction. About half an hour before the operation the nasal fossæ are packed with gauze which has been soaked in a 20 per cent. solution of cocaine hydrochloride and a 1 in 4,000 solution of adrenalin chloride. When the nose is being thus packed it is convenient to have the patient seated in a chair, but as soon as this has been done, he or she ought to lie down on a couch and rest quietly until the time of operation. This simple precaution will serve to prevent symptoms of faintness or collapse. On the one or two occasions in which I have seen symptoms of faintness supervene the patients had foolishly tried to maintain the erect posture. Another small point, attention to which may also help to prevent untoward symptoms, may be mentioned, and that is the gauze should not be too wet—if one might say so, the gauze should not be oversaturated. The gauze is allowed to soak up as much of the cocaine-adrenalin solution as it conveniently can, then any superfluous quantity is got rid of either by gentle pressure or by shaking. The packing is now proceeded with. If the gauze is so wet that the solution drips from it, when the patient assumes the recumbent attitude some of the solution is sure to trickle down the back of the throat and be swallowed. It is not improbable that in some cases untoward symptoms may arise from this cause which is quite an avoidable one. About half an hour after the nose has been packed in this manner one ought to be able to proceed with the operation, the two essential points accruing to the cocaine-adrenalin combination having been obtained, namely, anesthesia of the part and a bloodless field for operation. The method just described adequately fulfills these conditions.

With regard to the first, adequate anesthesia can in my opinion be obtained. I have carefully cross-examined several patients subsequent to the operation and I have found that any who do make complaints complain more of the uncomfortable feeling of having something done than of actual pain. They are generally quite quiet until one reaches the stage when bits of the septum (cartilaginous or bony) are being removed with cutting forceps. I am certain that at this stage the sense of hearing has much to do with the upsetting of the patient's equilibrium. It is probably just a little alarming to hear the chipping off of pieces of cartilage or bone from the septum of the nose, and the excellent conducting power of bone tends to give an exaggerated idea of any sounds thus made. A little persuasion will generally suffice to calm the patient.

As to the second point, namely, a bloodless field for operation, the cocaine-adrenalin combination applied in the manner indicated is quite effective. Seldom do we find that operation is interfered with by much bleeding. There are, however, one or two practical hints that should be noted if one desires to get the fullest benefit from this solution. In the first place too long a time should not elapse after the packing of the nose before the operation is done. In my opinon about half an hour's application of the cocaine-adrenalin gauze is the best. If there is a longer interval, say an hour or so, there will almost certainly be some trouble with the bleeding. If the delay is still longer the tendency to bleed will be much greater and the operation is considerably interfered with. Another important point is that the nose must really be packed. It is not enough to take a strip of gauze soaked in the solution and push it into the nose with a probe. It is absolutely necessary (if one desires to obtain the maximum anesthetic and hemostatic effect of the

solution) to see that the gauze is actually applied to and in contact with the mucoperiosteum of the septum and that the nasal fossæ are firmly packed. When one remembers that the septum may present all kinds of deviations it can readily be inferred that the accurate application of the gauze plug may not be an easy matter. The ideal method is to pack with the aid of vision, the nasal fossæ being well illuminated by light reflected from a forehead mirror. As a rule the person who packs the nose trusts to the sense of touch, and with a little care the septal bends and crooks can be fairly accurately followed. In the cases which have come under my notice it has only been necessary to put off the operation because of hemorrhage in one case, and here both the above points of technique had played a part. Through unforeseen circumstances the operation could not be started until quite two hours after the gauze pack had been inserted, and the so-called packing had been done by a novice, with the result that it had not been efficiently performed. As soon as the incision was made into the septal mucous membrane hemorrhage began, and there was a continuous ooze which rendered impossible any clear view of the site of operation. The application of adrenalin chloride solution (1 in 1,000) had no effect on this oozing. The operation was therefore postponed, but a few days later it was carried out without the slightest hitch or difficulty, care, of course, being taken to avoid faulty technique.

In the case just recorded it was also evident on the first occasion that the anesthetic effect was passing off, for the patient complained of pain directly the incision through the mucous membrane was made. This leads me to point out that the anesthetic effect of the cocaine does not last indefinitely, and it therefore behooves one to operate after a reasonable interval, and not to delay too long, otherwise the operation will not be painless. Remarks of a similar nature hold good as regards starting the operation too soon. The success of local anesthesia depends on sufficient time being allowed for the action of the drug to take place. Here patience is a virtue which leads to success. If the submucous resection operation be proceeded with too soon it will be found that anesthesia is imperfect and also that hemorrhage is fairly brisk. With the packing method of local anesthesia the operation should not be begun for at least twenty minutes after packing, and, as has been stated above, a half hour interval between packing and operation is the best in the great majority of cases. It is almost superfluous to mention that the best results are obtained with freshly made solutions. Old solutions, especially if they have been exposed to light, undergo decomposition, and they are inefficient for local anesthetic purposes.

In addition to the method just described in some detail there are two other methods for local anesthetization of the nasal cavity which find favor in certain quarters. One is the infiltration method, by which cocaine-adrenalin solution is injected into and under the mucoperiosteum of the nasal septum. This method has recently been enthusiastically praised by Seymour Jones (*British Medical Journal*, 1912, vol. 1, page 421). The technique adopted by him is rather elaborate. Both nasal passages are sprayed with a 20 per cent. solution of cocaine hydrochloride to which an equal quantity of 1 in 1,000 adrenalin chloride has been added. Next both sides of the septum are thoroughly rubbed with cotton wool mounted on wool carriers soaked in cocaine-hydrochloride 20 per cent. and adrenalin-chloride 1 in 1,000, equal parts. After, the injection is made. A solution of 0.40 cocaine-hydrochloride, 0.60 common salt, 200 distilled water (equal to 1/5 per cent. of cocaine hypochloride in normal saline), to which are added two drops adrenalin-chloride (1 in 1,000) to the cubic centimeter, is the solution used for injection. The author then details the exact technique of injection. Certain symptoms of circulatory disturbance usually supervene. "The patient becomes blanched, beads of perspiration exude, the heart thumps excessively, and occasionally, in fatty subjects and persons addicted to much smoking, it beats quite irregularly, intermitting one now and again. Others complain of intense pain in the lower part of the back and abdomen. I am inclined to believe this is due to great and tense pulsation of the abdominal aorta. A good many have headaches which last during the operation or supervene some hours after." These symptoms are, in the author's opinion, due to the action of the adrenalin, which causes a rise of peripheral pressure and stimulates the heart. Later there may be a fall of blood pressure and the patient partially collapses, due possibly to the late absorption of cocaine. In view of these symptoms it seems to me that the position taken up by this writer is not a very sound one. In the method which was first described untoward symptoms are conspicuous by their absence, and any symptoms which I have noticed have been extremely mild in comparison with the above. Attention to the points noted above does much to eliminate any ill effects during anesthetization by packing. In addition, the only bad effect which has occurred in cases observed by me has been slight headache, which is of short duration, and this was only complained of in a few cases.

Besides these symptoms, which appear to occur in almost every case anesthetized by the infiltration method, Jones reports three cases in which, during combined general and local anesthesia, alarming syncopal symptoms arose. The cases are as follows: "Case I.—A pale and anemic woman with a feeble circulation was fairly deeply anesthetized before the submucous injection was thrown in. About a minute after this the patient suddenly became intensely pallid, respiration ceased, and the pupils suddenly dilated. She was promptly inverted, and after about twenty or thirty seconds of anxious waiting she gave a sighing respiration, then a second, and finally recommenced breathing. Artificial respiration was not resorted to. Case II—This case occurred in a woman about a month later almost in the same way, except that the untoward symptoms appeared earlier. Inversion restored her breathing and the operation was completed. Case III—This was a case of endonasal operation for antral suppuration. The patient was rather deeply anesthetized, and I injected ½ c.c. of normal saline with a few drops of adrenalin (1 in 1,000) added into the anterior end of the inferior turbinate with the object of resecting this bloodlessly. Within ten seconds respiration ceased, the pulse was suppressed, and the pupils widely dilated. She was inverted immediately, and respiration gradually restored, the pulse becoming stronger by slow degrees." For my part, I have never made use of the injection method in the submucous operation, but a short time ago I had a rather alarming experience with a case in which some adrenalin solution was injected into the anterior ends of the inferior

turbinates. I have elsewhere (*The Prescriber,* April, 1912), placed the case on record, but as the subject is one of importance a short account may be here given. The case was that of a pale, anemic youth who came under observation for nasal obstruction for which turbinectomy and adenectomy were done. Combined local and general anesthesia was employed. Just before starting the operation a few minims of adrenalin solution (1 in 1,000) were injected into each inferior turbinate. The boy suddenly collapsed and exhibited all the signs of a severe syncopal attack which, at first glance, appeared fatal. Respiration was suspended, but the pulse (very rapid and small) could be felt at the wrist and, on auscultation, the heart sounds were easily heard. With artificial respiration and judicious stimulation gradual recovery took place, but it was almost five minutes before the danger stage was considered past. There were no further developments, and next day the boy was up and about as if nothing had happened. After this experience I have not cared to repeat the experiment. What causes the syncope one can only surmise. Jones suggests three possible explanations, anemia of the bulb, toxic action on the respiratory center, and spasm of the coronary arteries. It seems to me that the first affords quite a feasible explanation. At the German Congress of Internal Medicine last year Hirsch of Berlin pointed out that by injecting adrenalin into various organs in animals a rapid fall of temperature was produced (*Lancet,* June 10, 1911). Now this marked fall of body temperature can hardly be adequately explained by simple constriction of the peripheral vessels. Is it not likely that there is produced anemia of the bulb? If that is so, it is probable that the heat regulating center, which lies in the medulla oblongata, is interfered with. If that hypothesis be correct, one might further argue that other centers situated in that region, to wit, the respiratory and circulatory centers, would also be affected, resulting in the alarming train of symptoms already noted. Be the explanation what it may, there seems little doubt that such symptoms are directly attributable to the injection of adrenalin, and it is but right that a word of warning should be given in this connection.

Some workers who favor local anesthesia by injection substitute novocaine for cocaine. Bourgeois advocates this method (*Medical Press and Circular,* February 8, 1911), which is described as follows: "He first introduces gauze steeped in a solution of cocaine (1 in 30) and leaves it in contact five minutes. Then he injects a solution of novocaine (1 in 100) to which a few drops of a solution of adrenalin are added. This injection is limited to the zone of operation and begins at the furthest end of the nasal fossa. Immediately after the injection the fossa is plugged once more with the cocaine solution (1 in 30) and at the end of ten minutes insensibility is complete. The slight toxicity of novocaine renders secondary accidents almost impossible, while vasodilatation being much reduced, secondary hemorrhage is exceedingly rare."

Another method of local anesthetization in nasal cases is that associated with the name of Freer. Here crystals of cocaine-hydrochloride are directly rubbed up the mucous membrane of the nasal septum. This method is strongly recommended by J. Walker Wood (*British Medical Journal,* 1911, II. p. 1059), who proceeds as follows: "A few crystals of cocaine-hydrochlorate are picked up with a small cotton-wool mop saturated with adrenalin-chloride (1 in 1000), and gently rubbed into the mucous membrane of the septum on both sides. Three or four applications, extending over a period of about ten minutes, are usually sufficient to produce a perfect anesthesia." Adam of Hamilton, Scotland, has recently in a short note testified to the value of Freer's method (*British Medical Journal,* 1912, I, page 607). I fail to see that this has any special advantages over the method of packing, with the possible exception that one can control the dosage of the drug given. But does it not really amount to the application of a concentrated solution? The effect of the friction will be to stimulate secretion and the cocaine will undoubtedly be dissolved. Apparently in this method the mucous membrane of the septum is only anesthesized. The mucous lining of the alæ nasi is left untouched, and though there is no cutting in these parts it is surely hardly of advantage to allow them to remain sensitive.

It has already been pointed out that local anesthesia is the method of choice for the operation of submucous resection of the nasal septum, but in certain cases a combination of general and local anesthesia is necessary. The administration of the general anesthetic is carried out in the usual way. The preparation of the patient, the actual exhibition of the anesthetic, and the after-effects in no way markedly differ from what hold good in any general anesthetic case, and it is unnecessary to give details of such. The anesthetic used by me is either chloroform or a mixture of chloroform and ether. The anesthesia produced need not be deep surgical anesthesia. All that is required is sufficient anesthesia to dull the senses and abolish as far as posible reflex action. When the patient has been adequately anesthesized, an attempt may be made to keep up anesthesia by pumping the anesthetic through a Junker's tube placed in the mouth, but my experience has been that in many cases this does not act well.

There are several disadvantages in employing general anesthesia in this operation, and perhaps the greatest disadvantage is the bleeding. I have invariably found that when a general anesthetic is given hemorrhage is always more marked, and consequently operative measures are interfered with and the operation takes longer. Then there may of course be nausea and vomiting during the operation, whilst post-anesthetic vomiting frequently occurs. Other after symptoms such as headaches are more severe and more often met with when a general anesthetic has been employed. When the patient is under the influence of chloroform he is naturally unable to afford the surgeon any active assistance or cooperation, a valuable asset which can be realized when local anesthesia has been utilized. It has also to be remembered that this operation is sometimes not one of actual necessity, but is frequently undertaken to relieve some minor symptom. To subject any patient to the dangers of general anesthesia under such circumstances does not seem to me to be justifiable if local anesthesia could possibly suffice, and that there is a certain risk with a general anesthetic in every case must be admitted. However, in some a general anesthetic has to be given, for example, in the case of children and extremely nervous individuals. It is to a large extent a matter of temperament, and a child will often submit to the operation when an adult would make a great fuss. In looking over

some of my notes I find that of the last 84 cases which have claimed my attention 68 were done under local anesthesia, while in 16 combined local and general anesthesia was employed. Of these 16 cases 5 were children, and in several of the others further operative measures were being performed, such as adenectomy, turbinectomy, etc., so that there was greater need of general anesthesia. In only one case have I found it necessary to resort to general anesthesia after the operation has been partly done under local anesthesia, and in this case I believe the operation could have been concluded without the exhibition of chloroform by the exercise of a little persuasive exhortation. The case was rather a difficult one and necessitated much chiseling and punching of bone in the region of the maxillary crest and vomer. It was of traumatic origin resulting from a broken nose some years previously. As the case in question was that of a boy of 15 it was thought that the manipulations necessary for the removal of the bone would put too great a strain on the patient. The earlier procedures in this case had been carried out without the slightest difficulty. The youngest patient in this series in whom the operation was done under local anesthesia was a boy of 13—while in several boys and girls 14 and 15 years of age this form of anesthesia sufficed.

From the above considerations I am convinced that in the majority of cases no general anesthetic is required and that cocaine-adrenatin solution applied locally affords the necessary anesthesia. As to the mode of application I think the method first described is the best, and if properly carried out with every precaution to points of technique it should not fail. The advantages pertaining to it may be summed up as follows: (1) Efficient anesthesia and effective control of hemorrhage; (2) ease of application; and (3) freedom from ill-effects during or after operation.

VISUAL ACUITY AND THE MONTESSORI METHOD OF INSTRUCTING CHILDREN.

By SAMUEL HORTON BROWN, M. D.,

PHILADELPHIA.

Among the several recently devised methods of kindergarten instruction that have been brought to the notice of educators, none seems to have attracted the attention of the general public to the extent as has that employed by Dottoressa Maria Montessori in the several special schools in Rome, which bear her name. The system has been written about extensively in the technical journals and in the lay press, and discussed at great length. The reason of this attention is that Dottoressa Montessori claims to have devised a process whereby the pupils spontaneously break forth into reading and writing, "an explosion into writing," as she herself expresses it. Whether this is accomplished or not is a subject for the educators to determine, but since the method bids fair to be adopted in many of the lower schools and kindergartens, it is our duty as physicians to determine in how far it is influenced by physical and pathological factors.

It is therefore necessary to review briefly some of the prominent features of this system. In the first place it is stated that no coercion or even persuasion is employed; the child expresses himself only when he feels able to do so, and the means of expression is mastered through a series of toys and games, especially devised to develop the physical faculties in such a way that they respond quickly and accurately to the demands of the mind. This is similar in principle to other forms of kindergarten work, but different in technique, if the word may be so employed.

Madame Montessori began her life work as a physician, being said to be the first woman to receive a medical degree from the University of Rome. She occupied several positions in connection with the Italian Department of Education, having to do with the instruction of feeble-minded and defective children. It was while working along these lines that she evolved this system for educating normal as well as deficient children.

In Rome, Houses of Childhood, as they are called, have been built to accommodate this system and the children are oftentimes in the "Case dei Bambini" for quite a long period before any real lessons are assigned them. They are allowed to take part in any games they may elect, and to familiarize themselves gradually with their surroundings. The regulations insist that the child be neat and clean in person and in dress. When the children present themselves at school they are quietly inspected and their attention is gently called to any untidiness, the idea being to encourage the children to observe the tidiness of one another, but without deprecatory remarks, and by this means they acquire a habit of observing themselves. The Italian temperament doubtless permits this feature of the system to be absorbed and successfully carried out, but it is questionable whether American children having acquired the faculty of criticism could use it without the deprecatory remarks so much deplored by Madame Montessori.

The children are permitted to dabble in the water, but in such a way that washing of the hands and face are accomplished before the child is aware of the serious nature of the pastime. They are made to aid each other in buttoning their aprons. Light graduated exercises are employed to develop coordination. The free rhythm work as used in the American system is elaborated upon in this method. In addition to the songs, marches, and games the children learn to greet one another politely, and to sit properly and composedly in their chairs. They are taught to rise and reseat themselves gracefully and to move about the room with security and ease. The tables and chairs are not fastened to the floor in order to teach the children that it is necessary to move carefully among the furniture. Wherever possible, Madame favors the serving of school luncheons and takes advantage of such service to instruct the youngsters in the setting of the table, the serving of the meal, the washing of the dishes, and other similar duties, which the children soon learn to perform with considerable enjoyment.

Each morning the names of the qualified waitresses, dishwashers, etc., are placed upon a tablet and those who have learned to read announce these names to the others. When a child is able to carry safely a glass or a plate, this child is eligible for the position of waitress. As waiter or waitress the child develops gross coordination, which is further developed by the proper use of knives, forks, spoons and brooms.

Anthropological measurements are taken of the children in all these Case dei Bambini at regular intervals, and records are kept for comparison under the supervision of a physician. The birthday of the child is selected for this purpose. The stature is taken once a month on the date correspond-

ing to the birthday. The weight is taken once a week on the corresponding day, and once a year other details are recorded on the birthday. In this way the child is certain to become familiar with its birthday.

When the child has begun to feel perfectly at home amidst the surroundings and routine described the so-called Exercises of Practical Life are added to the course. Perhaps the introduction to these will consist of a number of light wooden embroidery frames which have pieces of fabric and other material fastened along their sides. These pieces are sometimes of leather, again of linen or dress material, and they may be hooked, laced, buttoned, or tied together, according to the arrangement of the particular squares. This aids in developing coordination and affords great interest to the youngster. This also enables the child to tie his own shoestrings and to button his own frock.

Following the use of the squares, the cylinders, the graduated rectangular blocks called the "Big Stair," the series of rods called the "Long Stair," and the graduated cubes called the "Tower," are employed. Madame Montessori refers to these as "a first floor in the education of the senses."

The cylinders are ten in number, and are fitted into a case such as is used for holding weights. These usually come in sets of three, although occasionally in sets of four. In the first set the pieces are all of equal length, but graduated in diameter; in the second, they are all of the same diameter, but graduated in length; in the third, both length and diameter vary, the cylindrical form alone remaining constant. Although the cylinders are of solid wood, each armed with a little brass button at the top for taking them out and putting them back into the holes of the case, the entire apparatus may be carried by the youngest child in the school.

The object of this series of cylinders is to cultivate the instinct that children have for arranging small objects in rows. In the practical application of the cylinders they are taken out of their case by the child and mixed up, after which he endeavors to replace them in their respective places.

The succeeding lesson is that having to do with the construction of the "Big Stair" out of the graduated rectangular blocks, which are made comparatively large, as the child depends upon its visual perception in this exercise to guide it. Here the form sense is brought into use, and if the child is the subject of any refraction errors it will be shown by the slow manner in which the child perfects itself in the exercise.

The next lesson in which the series of rods is used is called the "Long Stair." The children at first regard it as a game of blocks, but soon it forms the basis for lessons in counting, and through them elementary arithmetic is taught. The object of these exercises is that the child may learn to distinguish differences of form and dimension through the touch as well as by sight.

In her original work among defective children, Madame Montessori was greatly impressed by the acuity and delicacy of the sense of touch in children under seven years of age. After this age it undergoes a natural decline and is not so amenable to education as formerly. It is upon this fact that the larger part of the Montessori method depends; consequently the first exercises have to do with gross tactile impressions.

After the children pass through the hand-washing and bowl-washing stage, they are given a series of exercises in order to lead them to discriminate quickly and accurately between rough and smooth surfaces. The apparatus consists of a set of tablets and cards on which are mounted strips of rough and smooth paper. The teacher passes the fingers of the child over the rough and the smooth strips, indicating each by name as the fingers are drawn across it. The teacher then requests that either the rough or the smooth be given her by the pupil, in order to determine if the child has been able to appreciate and remember the difference. This exercise is also performed with the child blindfolded.

This simple exercise is elaborated upon until the child is able to distinguish, blindfolded, velvet, several qualities of silk, several grades of woolen goods, linen, cotton, and other fabrics. These exercises begin with two squares of strongly contrasting fabrics; the child is directed to feel each and then to match the test squares with the squares of similar fabric taken from a pile of assorted squares of fabric. The quality is first learned by the child and the names are learned later. According to all reports the children seem to enjoy this exercise immensely.

Exercises devised to teach the children to distinguish differences in weight are also a part of the system. The pupil first takes in each hand tablets of different weights and balances them upon his palms until he appreciates the difference. He is then blindfolded and allowed to select from a pile of weights those that appear to him to be of the same weight.

Following close upon the exercise to determine the values of rough and smooth surfaces, the system prescribes that the letters of the alphabet be cut out of metal or out of sandpaper. In the first instance the geometrical form of the letter may be cut out of the metal and the child directed to fill it in with crayon until familiar with the shape and with the name of the letter. In the case of the sandpaper letters, the letter is cut out of the rough paper and mounted on a glazed cardboard. The letter is shown to the child and named; then the child is made to trace the rough letter with the fingers, as in writing, the sound of the letter being given to the child at the same time. The movable alphabet, having the vowels in pink and the consonants in blue, is next used to educate the sense of sight as to the geometrical form of the letters.

Owing to the phonetic character of the spelling in the Italian language, these children eventually assemble these letters of their own accord and spontaneously break into writing words. Reading is brought about in the same way; a word is placed upon the board and the child analyzes it, calling the pronunciation of each letter as it appears to him, and the pupil is made to assemble these sounds so that a spoken word is formed.

The instruction in elementary colors is similar to that of Sequin, used for defective children; first the teacher shows the child the object and speaks the name of its color distinctly. Secondly, the name of the color is announced and the child is requested to give the object having that color to the teacher. Thirdly, the teacher points to the object and then requires the child to pronounce the name of its color.

Having briefly reviewed some of the more prominent features of Madame Montessori's method of instructing children, it is pertinent to inquire as to what extent a system of this character would in-

terest ophthalmologists, physicians, and those having to do with child culture institutions. Those of us who have had to do with school children of the larger cities are impressed with the great number of cases of defective vision in the children, due to errors of refraction and faulty development, and cannot but feel that the present system of elementary education (and also the advanced) demands too much from the ocular structures. In other words, it requires that the entire visual and psychovisual apparatus be absolutely normal before it is possible that any progress can be made in the child's education.

In accordance with this, kindergartners are instructed at great length in psychology, most of which has to do with physiological optics and ocular physiology. The exercises for the children necessarily have to do to a large extent with visual perceptions, and in so far as the vision is defective, in just so far is the child's education affected. The educators' responsibility is shifted to the ophthalmologist, who does his best to restore or rather develop normal vision in these children. Despite our very best efforts, and even in favorable cases, it may be a year or more before the visual units of the retina and visual tract are properly developed, during which time, of course, the presence of the tactile sense is ignored and the child's education is necessarily at a standstill. If, however, the child be so unfortunate as to be deaf, dumb, and blind, he or she will then become the inmate of an institution where this tactile sense will be developed, and his or her education will surpass that of many of these children who have only comparatively slight visual defects.

It would seem that if the wonderful results of Madame Montessori were accomplished in the children of the slums in Rome, where certainly it was impossible to prescribe glasses by the wholesale for the children, there would be some field for the application of the system here. While there can be no objection raised as to the caring for the sight of the school children as we are now doing in this country, it would appear to be along the line of rational progress to supplement our system of education by any innovations that would remove the strain from the eyes and that would enlist the activity of other special senses which are now allowed to remain latent. We are all familiar with the current hypercritical advice concerning the height of the desk, the type, the paper, the books, etc., and we have failed to note any material improvement in conditions, or even in the books which are giving the advice.

In making the comments and criticisms it is understood that the Montessori method does not stand alone in the character of its exercises or the results obtained. There are numerous American methods employed in different sections of the United States which are producing as wonderful benefits, but the bulk of the lay public, as well as the educators, have not appreciated the fact that it is possible to educate normal, as well as abnormal children, by means of the tactile sense as well as the visual sense. Systems such as Madame Montessori has devised, however, do not exact any very great strain upon the eyes, and thereby such systems enable us properly to develop the visual acuity in children who may be suffering from errors of refraction and undeveloped retinas.

1901 Mt. Vernon Street.

A CONTRIBUTION TO THE STUDY OF FOLIE À DEUX,

WITH REPORT OF A CASE.

By WILLIAM A. BOYD, B.S., M.D.,

WESTPORT, CONN.

ASSISTANT SUPERINTENDENT, THE WESTPORT SANITARIUM.

Definition.—There is no good corresponding English term for *folie à deux*. It might be termed a mental disorder occurring in two or more predisposed individuals, who have been intimately associated with each other. It is characterized by delusional ideas, particularly of a persecutory type, which may be transferred from one individual to another.

Synonyms.—"Communicated insanity" and "double insanity" are terms which have been used. The former does not cover all cases, as the French and English classifications are somewhat different; the latter term is inconvenient when, as not infrequently occurs, more than two persons are affected.

Types.—Three principal types have been mentioned and described in literature, namely: (1) imposed insanity, (2) simultaneous insanity, (3) communicated insanity.

Historical Sketch.[3]—This disorder was first mentioned by Baillarger but it was first accurately described by Lasèque and Falret[29] in 1877.

1. In describing the type known as imposed insanity or *folie imposée*, Lasèque and Falret stated that delusional ideas of one person might be transferred to another sane individual, but it was necessary that the two should have been intimately associated and free from counterbalancing influences, and that the delusional ideas should present some degree of probability in order that they might be accepted. They also noticed that the psychosis in the second individual did not run a typical course, but tended to disappear as soon as the two were separated.

2. Simultaneous insanity, or *folie simultané*, was first described by Regis[54] in 1881, who stated that this form of folie à deux consisted, not in the communication of a delusion from one person to another, but in its simultaneous appearance, and by reciprocal influence, in the predisposed individuals who are together. Regis stated that imitation may have a certain effect on weak mental organizations always ready for any occasional cause. This action might affect at the same time a large number, and as an illustration he mentions the famous epidemics of insanity in the Middle Ages. The most familiar illustration of this class in modern times, is the effect produced by the Revivalist. This form has not been accepted by some alienists as a true type of folie à deux, on account of the absence of evidence of mental contagion in the transmission of the psychosis from one person to the other. Diefendorf[9] states that there is no form of phychosis characteristic of simultaneous insanity. Several published cases have presented the clinical picture of manic-depressive insanity, some of exhaustion psychosis, and many of dementia precox. In his own experience, forms of dementia precox have predominated. *Folie gémellaire* (the insanity of twins) is one form of simultaneous insanity and was described by Ball[4] in 1884. Instances were cited in which two or more brothers or sisters, together or separated, have been affected simultaneously, and in an identical manner.

3. Communicated insanity, or *folie communiquée*,

was first described by Marandon de Montyel[36] in 1881. In this form the second individual accepts the delusional ideas of the first only after prolonged resistance, and the psychosis persists in the second even after the two have been separated. He states that it is not absolutely essential that both cases should present the same psychosis.

In addition to the three types already mentioned, another has been described by Lehmann[33] which he calls *folie induite* or induced insanity. It consists of the addition of new delusions of the original insanity of the patient, under the influence of his association with other patients.

Tuke[64] classified the disorder as follows: (1) cases in which an insane patient distinctly infects another person with the same mental disorder. (2) Cases in which a person becomes insane from companionship, not in consequence of direct transference of morbid ideas, but in consequence of the shock arising out of the painful impressions caused by witnessing the attack, or by the strain of nursing a patient. (3) Cases in which two or more persons become insane simultaneously from the same cause. (4) Cases in which one lunatic infects another lunatic with its special delusion. At the conclusion of an article on folie à deux, among other conclusions, Tuke arrived at the following: (1) In the majority of cases, those who become insane in consequence of association with the insane are neurotic or somewhat feeble-minded. (2) Females are more commonly affected than males. (3) The most common form which cases of communicated mental disorder assume is that of delusion, or of being entitled to property of which they are defrauded by their enemies. (4) A young person is more likely to adopt the delusions of an older person than vice versa, especially if the latter be a relative. (5) It is often difficult to determine to what extent the person who is the second to become insane affects in his turn the mental condition of the primary agent.

In reporting cases of communicated insanity most writers divide or classify those affected with this disorder into the active or parasite and the passive. In the case which I report, I regard the daughter as the active agent or parasite, and the mother as the passive agent or person infected, which is rather an exception to the rule. At the conclusion of this article is appended a somewhat complete bibliography of books and periodical literature upon this subject. I am indebted to the Librarian of the Surgeon General's office and to the Librarian of the New York Academy of Medicine for access to valuable material, and to Dr. A. R. Diefendorf for helpful suggestions in the preparation of this paper.

Report of Case: A mother and daughter came under my observation on the same day, August 3, 1911. The family and personal histories of each will be considered separately: the psychosis of both, of course, together.

Miss R. Age 24. Maternal aunt and mother insane. Had the usual diseases of childhood. Was educated at high school and at business college. As a girl she took little interest in reading, study, or music. By far the greater part of her time was taken up in assisting her mother with the household work. Her disposition was quiet. During her girlhood she would have mixed with young people in a normal way, but her mother objected to their coming to her home, saying that they were too much trouble and that entertaining required too much extra work. Soon after graduation she secured a position as stenographer, but her business career was very unstable. Within a period of five years she had worked for ten different firms. Some of these were temporary positions, but in the majority of cases she quit of her own accord for reasons which will be mentioned in the section of this paper pertaining to her psychosis. Her work had always been satisfactory and she had in her possession excellent letters of reference. The excuses which she gave her parents for leaving these positions were that her salary was too small, that she was substituting for another, and that the positions were temporary ones.

Mrs. R. Age 49. Maternal aunt insane. Mother very nervous. Daughter insane. Nothing unusual occurred during childhood or young womanhood. She received a common school education, marrying at 19; one child was the result of this union. An attack of pneumonia at 23 was followed by "kidney trouble." Her disposition before marriage was a cheerful and happy one, but she was very "nervous." Her domestic life was fairly happy, but she was "cranky" and irritable. Six years ago she stopped visiting her friends and neighbors and worried much because her hair began to fall out. Her menopause occurred about one year ago; since then her health has been poor and she has frequently complained of headaches.

The attack of the daughter was characterized by a gradual, insidious onset of about four years' duration. It was first noticed that she talked and acted strangely at times, was suspicious of others, and had ideas of reference. On several occasions she quit her position as stenographer, saying that the people with whom she worked had made slighting remarks about her work, laughed at her dress, and at Sunday school, on the street cars, and at the homes of relatives others made remarks about her. About the middle of June, 1911, there was a marked change in her condition, and I fix the acute onset as beginning about that date. She seemed more "nervous," her appetite was poor, and she could not sleep. She complained of "bad feelings" in her head, and declared that she was "much mixed up." She frequently became lacrymose because her father did not believe in her hallucinations and ideas of reference. These auditory hallucinations were prominent. She would close the door, talk in whispers, saying that some one was listening. She claimed to hear the voices of men outside the window, who, when she appeared at the door, said "there she is now." She feared that she would be arrested, taken away, locked up, and killed. She was suspicious of her food, and had hallucinations of touch. She had never been seen talking to herself, her conversation was always coherent and relevant, she displayed no suicidal or homicidal tendencies, and was never violent. No visual hallucinations were noted.

A word about the home life of these people may not seem out of place just here. The family consisted of father, mother, and daughter. They lived upon a farm, the father, a huckster, was away during the day, and often until late at night. As the mother discouraged the visits of her friends and neighbors, mother and daughter were thrown continually into each other's society, and consequently depended much upon each other for advice and sympathy. When the acute onset of the daughter took place, her mother was attacked with similar symptoms. Although she had been nervous for many years, and during her married life had been "cranky"

and irritable, she had shown no marked mental symptoms until that date. She would not eat, feared that something was going to happen—that she was going to be punished. She believed that her daughter had a "spell" over her which she could not break, and wanted the daughter sent away for fear that this influence might make her mad. She was self-willed, and would threaten to kill herself if her husband did not allow her to do as she pleased. She would often mutter to herself in a low tone of voice, and there was some retardation in speech and movement, and her emotional field was very unstable. Marked ideas of reference were present; she thought people were trying to injure herself and her daughter. She was suspicious of the conversation and actions of every one except her daughter. Auditory hallucinations were frequent. She heard voices under the window talking to her and about her. She also heard voices of people in the shrubbery about the house, who were eavesdropping, and whom she thought were planning to rob the house. Mother and daughter spent much of the time reading the Bible together; this was unusual. They would sit beside each other all day and often until after midnight, talking to each other of their imaginary troubles in whispers, fearing that they might be overheard. They believed that everyone was talking about them. The mother said that the neighbors called her daughter a bad character and that she would have to share the disgrace. They were superstitious, wanting the dog and cat killed and their blood sprinkled upon the doorsteps. They both firmly believed that their own presence about the house brought bad luck. They expressed the delusion that the farm was going to be taken away from them, and one very rainy day, without protection of umbrella or raincoat, they started to the house of their pastor to ask his intercession in this matter. Each patient seemed to wield a great influence over the other; the mother obeyed her daughter implicitly; the daughter in turn would not obey her father unless she first asked her mother's consent. By the fifth week after the acute onset, neither of the patients would do any housework, and the husband found it necessary to prepare his own meals.

On admission six weeks after the acute onset, a physical examination of the daughter was made. She was noted as a slender, poorly nourished young woman weighing only eighty-eight and one-half pounds. Her gait was steady, but she swayed slightly in the Romberg position; this, however, was probably due to weakness. There were slight tremors of extended fingers, tongue, and closed eyelids. A history of constipation. Mentally, on admission, she was noted as taking little interest in her surroundings; sat with eyes fixed upon the floor, replying to questions in monosyllables, in a slow, hesitating manner. Her answers were at times suspicious and evasive, and she would frequently ask, "What do you want to know that for?" She said that it was difficult for her to think at times and that her head "seemed to be in a whirl." Her memory was somewhat impaired both for recent and remote past. No hallucinations or delusions could be elicited. Orientation poor. Speech coherent.

Six weeks after the beginning of her attack the mother was examined, with the following findings: physically, a medium-sized, middle-aged, poorly nourished woman showing no physical abnormalities. Urine normal. Mentally: she could not answer questions, but sat seemingly absorbed in her own thoughts, gazing absently in front of her. She seemed confused, and it was impossible to elicit hallucinations or delusions. Her orientation was poor, and memory impaired.

At first the mother and daughter were allowed to remain together in the ward parlor. During this time they would sit side by side, quite abstracted, rarely, if ever, speaking to each other, but seemingly looking to each other for protection. At the end of a few days it was thought best to separate them. The daughter was allowed to remain with the other patients in the ward parlors, while the mother was put to bed in her room, where she could receive special nursing which her weakened and poorly nourished physical condition seemed to require. Seven weeks after the acute onset the daughter showed slight signs of improvement. Although she still ate sparingly she took more interest in her surroundings, and was more accessible in conversation, seemed to take some interest in the music, and took walks in the grounds with other patients. When examined mentally it was found that she was only partially oriented. She admitted that she had auditory hallucinations at home, but had not been troubled with voices talking about her since her arrival here. She said to the physician, "I do not feel just right, there is a peculiar feeling in my head; the whole of me feels peculiar; I am not strong and get tired easily; my head does not feel just right, heavy; my memory is not so awful clear; I am not perfectly well." There seemed to be some impairment of memory, her judgment was poor, and she had no insight into her condition. At this time the mother seemed to improve slightly also. When examined by the physician, she resisted gently, saying, "What does it all mean?" Her attention was hard to focus, her memory was defective, she was only partially oriented, and her apprehensions were intense. No auditory hallucinations could be elicited, but she expressed some vague delusion about the window curtains being changed, and other things being different in the room. It was necessary to urge her to eat, and although she had been taking a tonic she did not increase in weight and at this time weighed only eighty-seven and one-half pounds.

Ten weeks after the acute onset the daughter was allowed, at the request of her father, to leave to visit relatives for a few weeks. At this time she was very quiet, conversed in a relevant manner, but with a slight hesitation as if there was some retardation of thought or a slight memory defect. She slept well, her appetite was good, and she had gained slightly in weight. At this time the mother spent part of her time in bed, but was allowed to sit up part of the afternoon. She was evasive in her answers, was suspicious at times, there was some retardation in speech and action, and some memory defect was still present. The daughter was readmitted two and one-half months after the acute onset. After a pleasant visit with relatives she had returned home, where instead of improving she seemed to take less interest in herself and her surroundings and as her father could not remain at home with her he thought it best to return her to the hospital. When questioned by the physician she admitted having heard voices talking to her, and thought there was some beneficent influence growing out of her auditory hallucinations. She had no true insight into her condition, but said there was something she did not understand. She expressed many somatic complaints and her memory for recent and past events seemed to be impaired.

During this time the mother's mental condition had improved a little. She would occasionally become lacrymose because she was not allowed to go home. She seemed somewhat brighter, but did not care to enter into conversation with any one. Of course, during all this time, the mother and daughter were kept apart. In the fifth month after the beginning of the attack, against the advice of her physicians the mother was removed to her home by her husband. She had gained slightly in weight. Her mental condition was somewhat improved, in that she seemed to take more interest in her personal appearance and in her surroundings, her memory seemed clearer, she was not so lacrymose as formerly, conversed more freely, her appetite was improved, her sleep was more refreshing, and she denied her former hallucinations, but I did not consider her as being quite normal at this time. Two weeks after returning home, a message was received that she had improved very much after returning home and appeared to be practically normal. She was in a rather weak physical condition, however.

During the six weeks of the daughter's readmission, there was practically no improvement in her mental condition. She still presented apathy, faulty memory for recent and remote events, and limited content of thought. Her hallucinations and delusions could not be elicited. She continued seclusive and suspicious, refused to go to the dining room, had to be assisted in dressing and undressing, and was careless and untidy. She would sit or stand about the wards taking no interest in her surroundings. She would not talk unless addressed, and her replies were in monosyllables. Her memory and judgment were poor, and she had no insight into her condition. Nineteen weeks after her acute onset, at the request of her father, she was again removed to visit relatives. Several weeks after leaving here, a report from her relatives stated that the daughter had not improved at home, and that she had been sent to one of the State hospitals.

In this case, as in the majority of cases reported, there is the active agent, who in this case is the daughter, who had suffered from dementia precox of the hebephrenic type of some years' duration. It was not, however, until an acute exacerbation, that the mother, thrown in very close and dependent relationship, accepts the "crazy" symptoms of her daughter; that is, the delusions, hallucinations, and fear. It is worthy of note that the mother's case, during its development and course, was far more acute and profound and accompanied by more physical disturbance than that of the daughter.

WHAT PART SHOULD THE GENERAL PRACTITIONER TAKE IN THE CAMPAIGN FOR THE CONSERVATION OF VISION?*

By PERRY B. HOUGH, B.S., M.D.,

NEW YORK.

I THINK we are all agreed that preventive medicine is being developed on all sides at the present time, and that any study of the preservation of the health of the human body should include that of the organs of vision. For unless the vision is normal the rest of the body must work under a handicap, which, however small, is an item of expense to the public at large. I shall endeavor to take up the more common factors that cause loss of vision and show how they can be avoided or decreased.

Ophthalmia neonatorum is one of the most prolific causes of loss of vision. Up to 1882, when Credé made the statement that ophthalmia neonatorum could be prevented by the instillation of a drop of a 2 per cent. solution of nitrate of silver into the eyes at birth, statistics showed that from 10 to 30 per cent. of the inmates of blind asylums had lost their eyes from this cause. Since then, as this method of procedure has been followed more and more, we find a marked decrease until at the present time in New York ophthalmia neonatorum is a rare disease. It has been made a reportable disease by the New York Health Department, and all midwives are required to use the Credé method. The result is that in 32,201 births reported by them in six months and investigated by department nurses only twenty-three cases were found. During 1910, 129,080 births took place in New York and at the several eye hospitals and lying-in hospitals only 178 cases were reported. As to how many cases occurred in private practice we do not know, but we can be certain that if all men recognized the fact that a purulent conjunctivitis could be caused by other organisms than the gonococcus and would use this method at every birth the number of cases would be almost nil. If the infection occurs at birth the disease will occur before the fifth day, but if it occurs after that date the infection took place after birth. The severity of the infection varies with the infecting organism and its virulence. It may manifest itself as simply a mild infection with scanty secretion and very little swelling of the conjunctiva and lids, or it may go on to a marked edema of the conjunctiva, swelling of the lids and a profuse purulent secretion. The treatment is cleanliness—irrigating the eyes every half hour if necessary to keep them free from secretion. As to whether a solution of boric acid, bichloride, or normal saline is used I do not believe it makes much difference. Silver nitrate, 2 per cent. solution, should be used once a day. Cold compresses for half an hour two or three times a day will hasten recovery. In the severe cases the cold compresses should be applied for a half hour every two hours day and night and may occasionally have to be applied almost constantly. If the cornea becomes involved heat should be used instead of the cold. Personally I have great faith in the efficacy of argyrol, using a 30 per cent. solution in the beginning every two hours and decreasing the strength and frequency as the condition improves. If the treatment is begun early, as it should be, I do not think an eye should be lost; but when it is lost this is because of improper care.

Next to ophthalmia of the newborn is ophthalmia in adults. Here the prognosis is more grave and consequently one should strive harder to prevent infection. For this reason every patient with gonorrhea should be warned of the danger of infection not only to himself but to others, and of the absolute necessity of cleanliness at all times. When the infection has occurred the same line of treatment should apply, but here the cornea must be watched much more carefully and if the pressure of the lids is very great, as is shown by a tendency of the cornea to become steamy or hazy, the pressure must be relieved at once by incising the outer canthus. In this way many a cornea will be saved that would otherwise be lost.

Next in importance in many places is trachoma. In New York the problem is being worked out through the medium of school inspection, which tends to reach the cases before they have reached a chronic stage. All suspicious conjunctival cases are advised to consult an oculist and in this way early treatment is started. The success of the plan is shown by the small number of advanced cases in

*Read before the Society of the Alumni of the City (Charity) Hospital.

adults that are applying for treatment at the various eye hospitals. Of course the examination of immigrants has been of great importance in preventing new cases entering, so that it is now a question of curing the cases we have in our midst. This one can help to do if when they present themselves for treatment instead of simply giving them a solution of boric acid with which to bathe the eyes one will give a little more careful examination, and if in doubt send the patients to someone else to decide as to the proper treatment. In the hard follicular type an application of copper sulphate in the form of bluestone or a solution of bichloride (1 in 500) works very well, but operative treatment is more satisfactory. At home the best results seem to be obtained by using a solution of tannin in glycerin (15 grains to the ounce); or a solution of bichloride (1 in 5000) if there is no secretion; but if there is secretion argyrol 15 per cent. or another preparation of silver gives the best results. In the papillary type the ordinary operation of expression I believe does very little good and sometimes leaves the lids in a much thicker condition than before the operation. The medicinal treatment as outlined above gives much better results in the acute stage, while in the chronic stage the excision of the cartilage is often indicated. Cleanliness and the necessity of separate towels and handkerchiefs should be impressed on all suffering from this condition.

Another source of corneal trouble is among those who work at the emery wheel or in quarries or who use steel instruments. The necessity of cleanliness in the removal of foreign bodies from the cornea should be impressed on every one in these trades. Very often the chips are hot when they enter the cornea and are sterile, but if they are removed with a sharp nail or knife which is not clean, the cornea will be abraded and infected, and if not properly treated from the beginning the eye may be lost or the vision greatly impaired by the resulting scar. Happily this happens in only a small minority of cases, but there is a loss of vision in all, for if one examines these cases one will find that the cornea is studded with small opaque facets, the density depending upon the amount of damage done in the removal of the numerous chips of steel. The result is a loss in contour and transparency, leaving a cornea with irregular astigmatism which cannot be corrected with glasses. Hence the necessity of urging these men to wear shields. The worst cases are those caused by chips of stone or marble, because in these cases an unclean object enters the cornea and consequently the percentage of infections is large. I believe great care should be taken in the removal of all foreign bodies, and that the ordinary foreign body spud should not be used in every case. A set of different sizes should be kept and in selecting one we should use one whose point is smaller than the object to be removed. In this way the point can be inserted under it and one can lift it out without causing a large abrasion. After it has been removed the wound should be cauterized by using a solution of bichloride (1 to 500) applied with cotton wound on a toothpick. In addition I prescribe a solution of argyrol 10 per cent. to be used at home three times a day for a few days to render the conjunctival sac as free from pathogenic organisms as possible. This should be used until the wound is healed. Following this line of treatment I have observed no infections following their removal and have been able to cleanse infected wounds very readily.

Another disease that is very prone to attack the cornea is phlyctenular conjunctivitis and keratitis. This very often follows measles and the exanthemata and used to be spoken of as a scrofulous condition. It usually manifests itself by the presence of small yellowish-white blebs at the corneoscleral margin or small grayish spots of infiltration in the cornea. The eye is red, but the redness is around the cornea and not over the whole conjunctival surface as in pink eye. There is seldom any secretion, but there is a profuse lacrymation which is irritating to the nasal mucous membrane and sets up an eczema of the nares and lip. There is usually marked photophobia and pain. The course of the disease is obstinate. It may clear up in a few days only to break out again and run the same course a number of times, or the attacks may last for weeks. The cornea is often left very much scarred and irregular. The treatment is both local and constitutional.

Atropine will often relieve the photophobia and decrease the lacrymation. Calomel dusted into the eye has always been a standby, although for the past few years we have met with excellent results by using argyrol 15 per cent. three times a day. Internally the diet should be restricted to good wholesome food, milk, eggs, etc., and all sweets should be prohibited. Cod liver oil and the syrup of the iodide of iron seem to give the best results. Many believe there is a tuberculous taint in these cases; evidence of the presence of this disease in other parts of the body in these cases has been found many times.

Tuberculosis and hereditary syphilis may set up an inflammatory condition of the iris and cornea in children which runs a slow course, but under appropriate constitutional treatment this condition usually clears up. Locally hot applications and atropine are required until the acute symptoms subside. In adults there may occur an iritis as a result of traumatism, or as a complication of syphilis, rheumatism, or gonorrhea. Its importance lies in the necessity for proper diagnosis and early treatment. It must not be mistaken for glaucoma, as the treatment of the two are exactly opposite. In iritis there is a small pupil with usually some exudate into it, giving it a grayish appearance, while in glaucoma the pupil is dilated. In iritis the anterior chamber is normal in depth or may be deeper than normal, while in glaucoma it is very shallow or may be almost obliterated, the iris being crowded up against the cornea. In iritis the tension is normal or may be slightly increased, while in glaucoma the tension is markedly increased and the eye may be almost stony hard. In iritis the cornea is clear and sensitive, while in glaucoma it is steamy and insensitive.

The injection in iritis is circumcorneal and bright pink in color, while in glaucoma it may in addition be scleral and conjunctival and is more dusky. The pain in iritis radiates to the temple and forehead and is often worse at night, while in glaucoma the pain is more neuralgic and may extend over the whole side of the face or be referred to the teeth. Glaucoma is very often ushered in with an attack of vomiting.

The treatment of iritis is to try to break up the adhesions between the iris and the anterior capsule of the lens. For this purpose we use a strong solution of atropine (4 per cent.) once or twice a day and have the patient use a 1 per cent. solution at home every three hours at first. At the same time

that we are striving to dilate the pupil we apply hot compresses to favor the absorption of the exudate that is binding the iris to the lens. Appropriate constitutional treatment should be pushed at the same time. It is very important that the treatment should be begun early, otherwise the adhesions may become so strong that it is impossible to break them. We may have a pupil blocked with exudate and the vision will be destroyed. An iris tied down to the lens is very apt to have frequent relapses of inflammation and go on to degeneration. Iridectomy often gives relief, but is not always easily accomplished, as it is very easy to wound the lens and produce a traumatic cataract, or the iris tears easily and a clear pupil is not always secured.

In glaucoma the treatment is to contract the pupil, pulling it away from the cornea in order to open up the filtration angle at the corneoscleral junction and allow the passage of fluids out of the eye. Pilocarpine or eserin is used for this purpose. Leeches and hot compresses are applied to the temple. If these do not relieve the condition within a few hours an iridectomy is necessary to relieve the tension or the pressure on the optic nerve will produce a permanent loss of vision. If atropine is used in one of these eyes the only thing left is an immediate operation, as there is nothing that will counteract its action.

Another group of cases that we are seeing now are those of poisoning from wood alcohol. A number of cases of blindness and even death have been reported as the result of the action of this poison. Some of these cases were accidental, others were caused by the substitution of wood alcohol in cheap drinks, and a number resulted from the inhalation of fumes while the patient was at work with mixtures in which methyl alcohol was the principal ingredient, as in shellac. There is no excuse for the manufacture of wood alcohol now that denatured or grain alcohol may be brought into this country free of duty for use in the arts. We should warn our patients against its use and strive for the day when its manufacture will be forbidden. Unrecognized errors of refraction are often a serious menace not only to the health of the individual but also to the welfare of the community. The examination of the vision of school children is doing a great deal to check these errors, but there is still a large number of people who are in need of glasses and do not recognize it. Styes, chalazia, and blepharitis are usually due to uncorrected errors of refraction. A mild conjunctivitis that refuses to yield to treatment will often get well after proper glasses are worn. If one would test for both far and near the degree of vision of patients who are suffering from headache a great many of these patients would be relieved without loss of time of so-called bilious headaches and upset stomach and of the depressed heart, resulting from headache powders. It has been conclusively shown that a great many men and women have been driven to crime and vice because they have been unable to continue to use their eyes in school or follow the work they had been in the habit of doing. These results can and should be avoided if the general practitioner would observe his patients a little more closely and suggest a little sooner to the parents of the backward student that it would be well to have the eyes properly examined.

Another class of patients in which there is often serious loss of vision is in children with strabismus. The family physician has an important part to play here in destroying the prevalent idea that strabismus is caused by fright, habit, or one of the exanthemata, and that if let alone the child will outgrow it. In diphtheria or whooping-cough there may be a paralytic squint (and even these cases are rare), but the occurrence in these diseases of strabismus is usually a coincidence or the squint may have been slight or periodic and probably not noticed by the parents up to this time, after which it becomes constant. There is almost invariably an error of refraction with unequal vision and unequal refraction in the two eyes. The strain of trying to get clear vision in each eye results in a disturbance of the relation between accommodation and convergence, which usually go hand in hand, and as a result there is a squint. It is the rare exception for these cases to outgrow the condition. It is necessary to put the eyes in a condition as nearly normal as possible and then to reestablish normal relations between accommodation and convergence. If these cases are allowed to go untreated there results a continued contraction of the affected muscle in the squinting eye, a contracture takes place, and then operation is the only way the eyes can be made straight. But what happens to the vision in these cases? With one eye turning in, if both eyes were used at the same time, the patients will have double vision; but to avoid this nature ignores the image in the squinting eye and gradually from non-use the vision in this eye deteriorates. This goes on until finally nothing can be done to restore the vision.

In the great majority of these cases if they had been properly treated when the condition first began the eyes could have been straightened without an operation and with the use of glasses and proper exercise the vision often would have been greatly improved and sometimes made nearly normal. Even if the vision is not improved the eyes are straight and they are not the subject of ridicule and derision as we often see; but what is more important the patients are not discriminated against when they apply for a position and are not forced to accept labor much below what they would otherwise be qualified to do. Closely allied to these are the cases of muscle weakness, in which the eyes are still straight to outward appearance, yet often cause intense suffering. These cases are the ones that suffer from various nervous troubles, even bordering on insanity. In these cases there is always almost a history of difficulty in reading. Some of the patients complain of being unable to read for more than a few minutes before the eyes begin to ache and they are forced to stop; others complain of neuralgic pains, and still others of nausea and headache. My latest case complained of severe vertigo. If the patients are at all nervous, as they usually are, they soon begin to worry and imagine they are going to lose their sight and experience all the horrors following this dreadful thing. They consult opticians, and sometimes, I am sorry to say, oculists, without getting relief, until someone finally discovers the trouble and relieves them or if not relieved they become nervous wrecks. Examination shows very often that they are wearing their proper correction so far as their astigmatism and hyperopia or myopia are concerned, but further examination will very often show a difference in the vertical level of the two eyes requiring a prism to correct it and in addition a marked weakness of the muscles of convergence. Stereoscopic exercise

combined with the exercise of the convergence with prisms or pencil and the internal administration of increasing doses of the tincture of nux vomica up to the point of tolerance or the use of bromides have given me excellent results. Only this past summer a college girl was referred to me. She had broken down in her school work, and was extremely nervous, alternating between attacks of hysterical crying and melancholy until her friends feared she might attempt to take her life. Appropriate treatment combined with general tonics and outdoor life has worked so well that this fall she reentered college and is doing as well as any of her classmates. I have had so many of these cases in the past few years that I believe with Dr. Gould that a careful examination of the eyes, including the muscles, should be made in every case of nervous trouble and that appropriate treatment in conjunction with the nerve specialist or family physician will go a long way toward a cure.

In conclusion: I believe the man in general practice has an important rôle to play, as it is he who comes in contact with the great mass of the people. He ought to be able to diagnose the more common complaints and treat them. If too busy to give them the care they need he should take the time to advise the patients of the necessity of proper treatment and to refer them to some one who is qualified. Many times a patient is advised to have his eyes examined, but as to whether an oculist or an optician should be consulted is left to his own discretion, and we are often surprised at the amount of ignorance as to the difference between the two even among the well-to-do. The physician ought also to aid in educating his patients as to the care of the eyes and the necessity of proper treatment of the different conditions that may arise.

AN UNUSUAL CASE OF TABES WITH TOXIC COMPLICATIONS IN THE ETIOLOGY.

By TOM A. WILLIAMS, M.B., C.M., Edin.,

WASHINGTON, D. C.

CORRESPONDENCE MEMBER OF THE SOCIETY OF NEUROLOGY AND PSYCHOLOGY OF PARIS, NEUROLOGIST TO EPIPHANY FREE DISPENSARY.

A man of 56, seen with Drs. Fillebrown and Abbe, felt five years ago numbness in the toes and a dimness of sight. The numbness gradually became worse, ascending the legs. Two years ago, catheter life followed difficult urination and impotency. Since a year he has found it hard to rise from his hands and knees. Since a month, deafness is noticeable.

He has attributed his sickness to inhalation for the past ten years of wood alcohol in his work of testing thermometers. This ceased five years ago and amyl alcohol had to be inhaled for ten minutes daily. Breaking of ribs twice and of nose severely are thought of importance. Previous history is insignificant.

Examination.—Reflexes: Patellar exaggerated, Achilles diminished. Abdominal, left lower absent, others moderate. Cremaster diminished. Bulbocavernosus present and brisk, though hard to elicit.

Motility.—Standing on both feet slight swaying, cannot stand on right alone. Romberg on left. Walk ataxic when eyes are closed. Diadocokinesia normal.

Sensibility.—Temperature, attitudes, localization, and diapason intact. Pin prick lost in the feet, becoming less and less diminished in the legs, and normal in upper part of thigh. Light touch lost in an area an inch square over right internal condyle of femur. Deep pain diminished.

Special Senses.—Slight deafness, which has recently increased. Sight dimness of vision. Slight pallor of optic discs, especially of the left, and temporal side of the right.

Pupils.—The right hardly contracts, and is oblate above. The left contracts faintly, quickly recoiling.

The seroreaction of Wassermann is negative.

The cerebrospinal fluid was not examined for the lymphocytosis to be expected.

The psychic state is slightly exalted.

Diagnosis.—The impairment of the pupil reactions and the reflexes, the difficulty of micturition, the disturbances of the sensibility of the lower limbs with ataxia are not consistent with any toxic symptom complex, which would not spare homologous neuronal systems in other parts of the body. True tabes is the cause of the condition. That is to say, it is the result of an ingravescent radiculitis of leptomeningeal source leading to secondary degeneration of the spinal roots and their derivatives within the spinal cord. (See Naglotte's writings and the author's "Pathogenesis of Tabes Dorsalis," Amer. Jour. Med. Sciences, August, 1908.)

*Treatment.**—The success of intensive antiluetic treatment is demonstrated in many cases. It should always be tried in those which do not undergo a spontaneous arrest. Mouth medication is harmful, as the nutrition of such patients is already impaired. Salvarsan in some cases has been rapidly efficacious.

1758 K Street, N. W.

*See articles by the author in *American Journal of Dermatology*, 1912; *Virginia Semi-Monthly*, 1912; Medical Record, 1910; *International Clinics*, 1909

Syphilis and Pregnancy.—L. Mangiagalli believes that the birth of a macerated fetus is not always evidence of parental syphilis, but is generally presumptive evidence of infection of the mother. Maceration is only a physiological phenomenon due to the presence of the fetus in the amniotic fluid, with a certain temperature and without air. Examination of the tissues of the fetus may show the spirochetes; or changes in the internal organs of the nature of sclerosis may equally show the presence of syphilis. The syphilitic placenta is also very large, edematous, yellowish-gray and sclerotic; and the cord shows similar changes. It is a question whether syphilitic infection of the ovule or spermatozoon may occur. But it has been shown that the fetus may be infected through the placenta, with the production of congenital syphilis, for the spirochetes have been found in the placenta and in the cord. These organisms have been demonstrated in the testicle and spermatic passages, but not as yet in the spermatozoon. Hereditary dystrophy may also result from transmission of the poisons without the spirochetes. When the father is healthy, but the mother infected, infection reaches the fetus by way of the placenta. If both parents are healthy at conception, and infected later than the sixth month, the fetus may still be healthy. It may be safely nursed by its mother since it possesses a sort of immunity conferred by the mother. The transmissibility of the disease lessens with time, especially in the male. The female may continue to abort long after the father seems to be healthy. As to treatment of the fetus, this should be carried out directly by means of mercurial inunction and not through the milk of the mother, since this method is too slow.—*La Riforma Medica.*

THE FATE OF SYPHILITIC PATIENTS.

EVERY physician has probably at some time or other wondered what happens to the numerous patients infected with syphilis that he sees in the dispensary classes and in the hospital wards. For most of us are fairly certain that the disease is not eradicated in the greater number of these patients by the treatment they usually obtain; external circumstances often prevent the adoption of most radical methods of cure, such as intramuscular injections of mercury, or the administration of salvarsan, while the patients themselves are very apt to drop treatment as soon as the external manifestations of the disease have disappeared. Of course, hospital men see numerous cases of cardiac and arterial disease, of degenerations of the nervous system, of psychoses, for which syphilis is primarily responsible. But these patients are rarely the same that have been treated in the hospital or dispensary in the earlier stages of their disease. Our shifting population, and the curious tendency of the classes that form the great majority of hospital patients to patronize now one now another institution, prevent any extended observations.

Conditions are quite different in the small university towns of Germany, where the whole pathological material of the town and environs frequently passes through one clinic, and thanks to the more paternal forms of government patients can be traced and observed for many years. These favorable circumstances have prompted Dr. Marie Kaufmann-Wolf to trace the fate of syphilitic patients observed by Fleiner in the Heidelberg Clinic in 1891, her results appearing in a paper in a recent issue of the *Zeitschrift für klinische Medizin* (Volume 75, Nos. 3 and 4).

Fleiner described at the time twenty-one cases of "occult" syphilis in women, that is, the tertiary stage of the disease without any history of the primary or secondary evidences of it. Of these twenty-one, nineteen were traced by Dr. Kaufmann-Wolf twenty years later; as many of these women were married at the time or married later the fate of forty-five persons altogether, most of them surely and a few possibly infected with syphilis, was studied.

Five of the women died, the causes of death being bronchiectasis with syphilitic tracheitis, "dropsy," syphilitic cerebrospinal meningitis, pneumonia, and tabes dorsalis. These causes, of course, show what intimate connection syphilis had with the death of these patients. Ten of the men died, the causes of death being apoplexy in three cases, pneumonia in two, cardiorenal disease in one, tabes dorsalis in one, "dropsy" in one, and accident in the remaining two. The striking thing in this mortality is the frequency of disease of the circulatory system (apoplexy) as compared with the late syphilitic manifestations in women. Many of these deaths occurred under circumstances in which autopsy could be had, so that the diagnoses represent much more exactly the true state of things than is usually the case.

It was also shown that though quite thoroughly treated, according to the general hospital and dispensary standards, these patients were later capable of infecting their husbands or wives, gave birth to children in whom the mortality was much above the average, and also showed much higher than the average number of abortions and still births. Sterility, too, was very common among them.

The results of this study are not very gratifying. They show how little our old methods of treatment were really curative of the disease when carried out among the dispensary and hospital patients, and this fact is quite in keeping with the laboratory evidence given by the frequent presence of a strongly positive Wassermann reaction in patients presumably well treated.

Salvarsan, of course, is the new factor which may change the state of affairs. It may be that repeated injections of this remedy, which certainly can be made within a much shorter period of time than the treatment with mercury requires, will give better results in the future. The chief heed is careful observation and registration of results, which heed, we fear, was quite generally neglected in the first enthusiastic use of the remedy. One hundred cases of syphilis, treated with salvarsan, and carefully observed for a long time are better subjects for publication than the thousands in which one or two injections produced regression of symptoms and which have been talked of *ad nauseam* in the recent medical literature.

POISONING BY TEA.

IT is only in comparatively recent times that tea drinking has been at all prevalent in this country. Coffee is the national drink and is more largely consumed by far than any other beverage. But tea drinking is making great strides, the reason for which is not hard to find. The advantages of tea over coffee as a stimulating and cheering drink do not consist in a superiority of its component parts but in the fact that a good tea can be more easily produced than a good coffee and that it is more easily made than coffee. A very great deal of the virtue of coffee consists in the manner in which it is converted into a beverage, and seldom is the art carried out efficiently. Many of the concoctions which are sold as coffee in restaurants and consumed in private houses are not worthy of the name. On the other hand, tea is easily made, the chief point being that the water used for the infusion boils, and that the infusion is drunk when fresh and not allowed to stand.

However, there are occasions and these not infrequent, when tea drinking is harmful. Tea poisoning is a more or less common condition in those countries in which the habit of drinking tea is prevalent, as in England for instance. Among the working classes the women often become addicted to the tea habit and not only drink to excess, sipping tea throughout the day, but drink it in such a state that the poisonous properties are most evident. The tea is in a stewed condition, the pot being kept on the stove the whole day. Men, too, who work at indoor trades and at trades which from their nature tend to create thirst, often become excessive tea drinkers.

It is probable that in most cases of chronic tea poisoning the symptoms come on very gradually, but in the later stages increase rapidly. Discoloration of the skin is a not uncommon symptom, combined with dilatation of the colon and constipation. According to Weild (*Medical Press and Circular,* May 15, 1912), this discoloration is due to some toxin arising from disturbances of digestion, and not to the direct action of any absorbed constituent of the tea, although doubtless the frequent flushing due to the tea greatly assists the action upon the skin. The pigment is not a deposit in the skin, but a product of the skin. Occasionally a patient will complain of polyuria, but there is only one pathognomonic sign of tea excess and this is not present in all cases: this sign is the odor of the breath. The smell is something like that of old books, musty. The cardiac symptoms are more akin to tobacco poisoning than to those of alcoholism, the symptoms of nervous derangement predominating over the signs of muscular degeneration. Injudicious indulgence of badly prepared tea is also the cause of much nervous atonic dyspepsia. According to Weild, for the majority of people, tea, properly prepared and taken in moderate quantities, is not only harmless but useful. Yet a glance at the pharmacology of two of the active ingredients of tea, caffeine and tannin, will show that excess of either may be expected to produce a serious disturbance in health. The disturbance, although varying greatly in degree, is so consistent in form that tea poisoning should rarely be overlooked. As is the case with all foods and beverages, but to a greater extent than with many, care in preparation and moderation in consumption are essential in averting the evil effects of indulgence in tea.

COLOR-BLINDNESS AND DISASTERS AT SEA AND ON LAND.

Carelessness and incompetence continue their appalling toll of human victims. The uncanny echoes of the *Titanic* wreck have not yet entirely abated. The congressional committee has completed its investigation and has made a report, partly placing the responsibility and suggesting many excellent recommendations for the prevention of similar calamities in the future. The English Board of Trade has also ended a patient though painful inquiry and its verdict and recommendations are awaited with interest on both sides of the Atlantic. In connection with governmental responsibility in the physical examination of those placed in charge of merchant vessels, the remarks made by F. W. Edridge-Green (*Lancet,* June 22, 1912) in reporting a case of color-blindness merit close attention. This observer, who is probably to-day the greatest authority on color-blindness, has invented a lantern with which by the use of various colors and apertures of different sizes, the defect of color-blindness can be easily discovered under conditions such as those that naturally prevail on the railway and at sea. The official test of the Board of Trade is an improved Holmgren wool test. Of eminent significance with reference to the fallibility of this test is the fact that an individual who, when examined with the largest aperture of the Edridge-Green lantern, mistook red for green, and *vice versa,* was able nevertheless to pick out and match correctly all the five test colors of the Holmgren method, in which color names are not used. This was a very dangerous case of color-blindness, in which the test used officially by the Board of Trade failed completely. It is pointed out that while many color-blind people are able to match colors with accuracy, they are unable to name the colors correctly, particularly if they are examined under conditions that naturally prevail, such as the presence of mist or imperfect illumination, and the varying effects of distance, and size of the colored object.

Of greater significance is the fact emphasized by Edridge-Green, that "not a single medical man either on the first examination or on appeal is employed by the Board of Trade." There can be little wonder that accidents occur at sea if this is an example of the supervision over the personnel of the merchant marine which has been exercised by our English cousins and in which respect we are probably no less culpable. One of the first reforms that should grow out of the recent dire sacrifice to neglect and folly should be the institution of rigid methods of examination of those to whom the care of thousands of lives are entrusted at sea and on land. The Edridge-Green lantern has been adopted by the British admiralty, but the Board of Trade still clings to the Holmgren test, which, "in addition to rejecting many normal-sighted persons, allows half or more than half of those who are dangerously color-blind to pass."

THE BEST WAY TO GET RID OF THE FLY.

Something like a billion flies were killed in the campaign of 1911, seven million in Washington, D. C., alone. This certainly is prodigious slaughter, and the figures are impressive—until we consider the number that escaped the executioners. Dr. Howard of the Bureau of Entomology has taken his pencil in hand: In the luxuriant climate of the national capital twelve generations of flies are hatched in a single summer. A single over-wintering mother will start, say about April 15, with an average brood of 120. If all these eggs should hatch and in their turn reproduce in the like ratio the end of the fly season would see the progeny of that one mother fly making up a tidy genealogical tree of some 1,096,181,249,311,720,000,000,000,000

branches, twigs and budlets. And as each female usually lays four batches of eggs, their unchecked development through twelve generations would make a mass of flies measuring 268,778,165,861 cubic miles, or considerable more than the total size of the earth. Fortunately there are many things destructive to eggs, larvæ, and adult flies, so the number of the latter is kept down to a possible figure.

Various communities are paying for dead flies —so much for a quart measure of them, so much for a gill (1,600 to the gill). If one could conceive all of the flies in existence being caught and paid for (and the hunters given a living wage) every treasury on earth would go insolvent. One must conclude, then, that the only way to get rid of flies is to get rid of the filth and the refuse which are their natural environment and pabulum. Your fly is the ideal mixer; filth and food are alike congenial to him. Not himself a disease-breeder, he is, nevertheless, the possible carrier of the specific causes of tuberculosis, typhoid fever, the summer diarrheas of infants, diphtheria, and in fact any or all germ diseases. So flies must, beyond all else, be kept from the sick room.

The fly is a natural scavenger; and scavengers have a reason for existence. Let her be killed by all means, but before relying on this alone we should follow her up to her breeding place (which is seldom beyond 300 to 500 feet away), and then make that place decent and sanitary. One should not rest content with killing the fly but should get rid of the places where she lays her eggs—the unsanitary closets, the manure heap, the uncovered garbage can, the putrescent dead dog and horse on the public highway. All refuse and decaying material and all vegetable and table waste should be removed and be burned or covered with lime or kerosene oil. All garbage cans must be covered or screened, or their contents sprinkled with kerosene or lime. The sewage system must be in good order, up-to-date, not leaking, not exposed; kerosene should be poured into drains. Manure should be put into tight pits or vaults, with an outer door from which it can be shoveled away; a barrel of chloride of lime is to be constantly at hand, from which each deposit of manure should be sprinkled. Shallow dishes should be placed about the house, one in each room, containing each two teaspoonfuls of formaldehyde to a pint (two tumblers) of water; or a teaspoonful of bichromate of potassium in a quarter tumblerful of water and sweetened with plenty of sugar. Pyrethrum powder burned in a room stupifies the flies so that they fall to the floor, whence they can be gathered up and burned, or sold if the market rates make it worth the while. All food and drink must be screened or covered in some way; all windows in dining-room and kitchen doors must be screened. Groceries, fruit stores, meat and fish stores must have their wares screened, and above all things else flies must not get near the milk. The American people are much impressed by slogans: "Swat the fly" is disgusting and suggestive of cruelty in the mind of the boy already so predisposed; a better one is "No filth, no flies"; and no disease.

Chondroituria.

When urine is tested for albumin with a few drops of acetic acid, the opalescence which forms in positive cases is due to an insoluble combination of albumin with chondroitin sulphuric acid, as may be shown by the fact that when these urines are first treated with chloroform, which extracts the albumin, no opalescence results. In orthostatic albuminuria the nocturnal urine is usually free from albumin, so that no precipitate results from adding acetic acid. But if a little serum albumin is added the reaction is very marked, showing that chondroituria is a phenomenon associated with orthostatic albuminuria. At a recent session of the K. K. Gessellschaft der Aerzte of Vienna (*Münchener medizinische Wochenschrift*, June 11) Politzer announced that he had found chondroituria in five cases of orthostatic albuminuria. He had also noted a frequent clinical association of the latter with a tendency to angina, and had also found chondroituria associated with this tendency, thus showing a sort of symptomatic triad. In severe anginæ, in endocarditis, etc., he had found chondroituria, albuminuria, or both conjoined. In actual nephritis we find chondroituria, but the acid substance is not precipitated with acetic acid until a certain quantity of albumin has first been taken out of solution. This behavior is associated somehow with the fact that the degenerated renal epithelia form chondroitin sulphuric acid, some of which enters the blood. This is never the case when mere functional albuminuria exists. The same substance occurs in pleuritic exudate, but pleurisy is not accompanied with either albuminuria or chondroituria.

News of the Week.

Plague in Cuba.—The existence of bubonic plague in Havana was definitely determined on July 6 when a patient who had been under observation a Las Animas Hospital for three days was declared to be suffering from the true disease. Three other patients had previously died in the hospital with practically the same symptoms. The Secretary of Sanitation has ordered extensive fumigation which, if necessary, will be extended over the entire city, and the rat-killing squad of the Health Department has been largely reinforced. In Porto Rico also a few deaths have occurred from the disease, and there the situation has been taken in hand by the Public Health and Marine Hospital Service, Passed Assistant Surgeon R. H. Creel being in command.

Enforcing the Food and Drugs Act.—The Secretary of Agriculture calls attention to the fact that during the months of April, May, and June, 1912, more than five hundred cases were reported by his department to the Attorney General for prosecution under the Pure Food and Drugs Act. This is one-eighth of the total number reported since January 1, 1907, when the act became effective, double the number reported during the same period last year, and 25 per cent. greater than the number reported during the first quarter of 1912.

The Two Platforms.—The subject of the public health and its safeguarding is touched upon in the platforms adopted at Chicago and at Baltimore. The latter contains the following plank: *"Pure Food and Public Health.*—We reaffirm our previous declarations advocating the union and strengthening of the various Governmental agen-

cies relating to pure foods, quarantine, vital statistics, and human health. Thus united and administered without partiality to or discrimination against any school of medicine or system of healing, they would constitute a single health service, not subordinated to any commercial or financial interests, but devoted exclusively to the conservation of human life and efficiency. Moreover, this health service should cooperate with the health agencies of our various States and cities, without interference with their prerogatives or with the freedom of individuals to employ such medical or hygienic aid as they may see fit."

The Republican declaration reads as follows: "*The Public Health.*—The Republican party is now, as always, a party of advanced and constructive statesmanship. It is prepared to go forward with the solution of those new questions which social, economic, and political development have brought into the forefront of the nation's interest. It will strive not only in the nation but in the several States to enact the necessary legislation to safeguard the public health, to limit effectively the labor of women and children and to protect wage earners engaged in dangerous occupations; to enact comprehensive and generous workmen's compensation laws in place of the present wasteful and unjust system of employers' liability, and in all possible ways to satisfy the just demands of the people for the study and solution of the complex and constantly changing problems of social welfare."

The Milk Commission to Work with the Department of Health.—The New York Board of Health has accepted an offer from the New York Milk Committee for extensive cooperation in the visiting of municipal milk stations by the doctors who are serving on the sub-committee for the reduction of infant mortality. The medical members of this committee will visit the city's milk stations at regular intervals and will submit detailed reports in writing of their observations. The committee has also appointed persons skilled in statistical work to assist in the supervision and checking up of milk station reports and in the collection of data for reports and public statements. In addition, the committee has appointed an executive secretary to act as an intermediary between the Department of Health and the recently organized Babies' Welfare Association, in the endeavor to bring about the best sort of cooperation between the city and the private agencies in the work of reducing infant mortality. This association reports that there are eighty-eight milk stations now in operation in the city, and that more than twice as many infants are being cared for as a year ago. Of the 150 organizations in the city engaged in work of one kind or another in behalf of infants, over thirty have already joined the Welfare Association, and it is expected that this number will be much increased during the summer and that through this extensive cooperation a new record of infant mortality will be established.

New Hospital Buildings.—The Metropolitan Hospital on Blackwell's Island, New York, is to be enlarged by the erection of a three-story and attic kitchen and dining hall on the west side of the Island. The building will be of stone and will be fireproof with a frontage of 50 feet and a depth of 128 feet. The cost is estimated at about $125,000.

The New York Dispensary has taken title to the plot numbered 34 and 36 Spring street, now used as a coal yard, which it will improve by the erection of a two-story building. The dispensary will occupy the new quarters as soon as they are completed, its removal from the present site on Worth street being made necessary because of the acquirement of the plot by the city as a part of the proposed court house site and civic center.

Gifts to Charity.—By the will of Mr. Charles Henry Marshall of New York, who died in Paris recently, the Darrach Home for Crippled Children of New York receives a bequest of $5,000 for the endowment of a bed in memory of the testator's daughter, Evelyn Isabella Marshall.

Floating Hospital.—The nineteenth season of Boston's Floating Hospital trips down the bay was successfully inaugurated on June 29, when fifty-five babies with their mothers were given a day on the water.

To Borrow Gorgas.—The Government of Ecuador has decided to clean up the port of Guayaquil, where yellow fever has existed for some time, and to that end has asked the United States to assign Col. William C. Gorgas, sanitary officer of the Canal Zone, with some of his assistants, to make a survey of the port and advise a plan to be followed. The request is under advisement and will probably be granted by special act of Congress.

Civil Service.—The New York State Civil Service Commission announces an examination to be held on July 27 for the purpose of filling the position of medical interne at a salary of $1,000 per annum and maintenance. Details may be obtained by application to the Commission at Albany, N. Y.

New Cattle Serum.—Prof. Wilhelm Grugel of the University of Rostock, Germany, has announced that he has succeeded in identifying the bacillus, which is the cause of foot and mouth disease in cattle and also in preparing a serum rendering cattle immune. The serum is not curative but has been used as a preventive with good results.

Sex Hygiene.—The American Federation of Sex Hygiene was incorporated in New York State on July 1 to operate throughout the country. The purpose of the corporation is the voluntary education of the public in the physiology and hygiene of sex, including the study and application of every means, educational, sanitary, moral, and legislative, for the prevention of vice and its diseases. The directors include many well known physicians and social workers. The federation will have its chief office in New York City.

City Death Rate.—During the week ending June 29 there occurred in New York City 1,233 deaths, as against 1,212 during the same week of 1912. In spite of this absolute increase, however, the allowance made for the increase of population is sufficient to make a reduction of 26 points in the death rate per thousand. A comparison of the totals for the principal causes of death in the two weeks cited in the report shows only slight variations except in the case of Bright's disease and nephritis, which caused 63 deaths during this period in 1911 and 102 in 1912.

Ward's Island Fire.—The Psychiatric Department of the Manhattan State Hospital on Ward's Island, New York, was destroyed by a fire of uncertain origin on the evening of July 3. The building was used entirely for research work under Dr. A. P. Hoch, and the ward buildings were not damaged by the flames, though as a matter of precaution some 400 women patients in the Verplanck

Pavilion adjoining the burning building were marshalled under guard to other quarters. Squads of police were sent from the city to the island to be in readiness in case of serious emergency, but fortunately their services were not required. The chief loss lies in the destruction of the library of some 3,000 or 4,000 volumes on psychiatry and of invaluable pathological preparations.

Medical School of Maine.—A number of changes in the faculty of the Medical School of Maine at Brunswick have been announced, among them the appointments of Dr. Alfred King as professor of surgery; of Dr. Alfred Mitchell, Jr., as professor of genitourinary surgery; of Dr. G. A. Pudor as professor of dermatology; of Dr. Gilman Davis as professor of diseases of the nose and throat; of Dr. F. P. Webster as professor of diseases of children; of Dr. Franklin Conant Payson as lecturer on medical jurisprudence, and of Dr. Nathaniel E. Loomis as assistant professor of chemistry. The school conferred the degree of M.D. upon eleven graduates at the annual commencement exercises on June 26.

The Rockefeller Institute.—The resignation of Mr. Jerome D. Green as general manager of the Rockefeller Institute for Medical Research has been announced. Mr. Green will be succeeded by Mr. Henry James, 2d, a son of the late Prof. William James, and a graduate of Harvard College in 1899 and of the Harvard Law School in 1904.

Dr. Jay F. Schamberg has resigned as assistant diagnostician to the Philadelphia Board of Health, owing to the press of private work. It is proposed to distribute the work hitherto performed by Dr. Schamberg among four associate diagnosticians, to be promoted from assistant medical inspectorships. Dr. Wm. M. Welch is chief diagnostician to the Board of Health.

Dr. William Pepper has been appointed dean of the Medical Department of the University of Pennsylvania in succession to Dr. Allen J. Smith resigned. He is a son of the late Dr. Wm. Pepper, for many years provost of the university. He was graduated from the medical department of the university in the class of 1897 and he has for several years been professor of clinical pathology in the university.

Dr. Knopf's Tuberculosis Manual.—The new (seventh) edition of Dr. S. A. Knopf's International Prize Essay, "Tuberculosis as a Disease of the Masses and How to Combat It," has just been translated into French by Dr. Eugene Grenier of the Bruchesi Tuberculosis Institute of Montreal. The proceeds of the sale of this book will be for the benefit of the institute. The first translation of a former edition into French appeared some years ago in Paris. Dr. Grenier's new French-Canadian translation represents the twenty-eighth foreign edition which, with the seven American ones, makes 35 editions in 24 different languages, which have appeared within the last ten years. They are: The American (7), Arabic, Bohemian, Brazilian, Bulgarian, Canadian, Chinese (2), Dutch, English, Finnish, French, German, Hebrew, Hindu, Hungarian, Icelandic, Italian (2), Japanese, Mexican, Norwegian, Polish, Russian (2), Serbian, Spanish, Swedish, and Turkish. Since the book was written, mainly for the education of the laity, this unusually large circulation speaks well for the world-wide interest of the masses in tuberculosis, in whose interest the Berlin International Tuberculosis Congress offered and awarded the prize.

Illinois State Board Examinations.—At a meeting of the Illinois State Board of Health, held June 29, the following resolution was adopted: "After this date the Illinois State Board of Health will require candidates from other States, seeking license through reciprocity, to pass an examination in the subject of materia medica or practice, or both, when an examination in such subject or subjects has not been exacted of the candidate by the board of the State from which he comes."

Cost of Insane Aliens.—In the investigation of this subject, which has received much attention lately, it has been stated that of the patients in the Manhattan State Hospital, New York, over 1900 are aliens, and that the cost of their maintenance is about $341,000 a year or a per capita cost of about $184. The general average throughout the State hospitals is said to be $200 per capita. The Manhattan Hospital at present houses 4,720 patients, although its capacity is supposed to be only 3,596. These facts were brought forward by Dr. Mabon at a meeting of the State Insanity Commission held at the hospital on July 1. It has also been estimated that in New York State more than 50 per cent. of native born insane patients are the children of foreign-born parents.

Chattahoochee Valley Medical and Surgical Association.—The twelfth semi-annual session of this society will be held at Atlanta, Ga., on July 16 and 17, 1912, under the presidency of Dr. George M. Niles of Atlanta. Dr. W. J. Love of Opelika, Ala., is the secretary and treasurer of the society.

Des Moines Valley Medical Association.—At the forty-ninth annual meeting of this society held in Ottumwa, Ia., on June 20, the following officers were elected: *President,* Dr. James W. Osborn, Des Moines; *Vice-Presidents,* Dr. Clyde A. Henry, Farson, and Dr. Elias B. Howell, Ottumwa; *Secretary-Treasurer,* Dr. Fred W. Bowles, Ottumwa.

Bridgewater Medical Club.—At a meeting held in East Bridgewater, Mass., on June 27, the Bridgewater Medical Club was organized with the following officers: *President,* Dr. Charles S. Millet, Brockton; *Vice-President,* Dr. W. C. Whiting; *Secretary,* Dr. Arthur W. Carr, Bridgewater; *Treasurer,* Dr. Allen L. Shirley, East Bridgewater.

Obituary Notes.—Dr. Ellis Vanderslice Ivey, who was killed in a railroad accident at Corning, N. Y., on July 4, was an interne at Bellevue Hospital, New York, having been appointed to take charge of the school for midwives after finishing a three months' service as assistant resident obstetrician at the Sloane Hospital for Women. Dr. Ivey was born in Suffolk, Va., twenty-seven years ago, and was graduated from the University of Pennsylvania, Department of Medicine, in 1910.

Dr. George Washington Tobias of New York, a graduate of the Bellevue Hospital Medical College in 1877, died at his home on July 4, aged 71 years.

Dr. William Hailes of Albany, N. Y., a graduate of the Albany Medical College in 1870, attending surgeon to the Albany and St. Peter's Hospitals, and emeritus professor of pathological anatomy and histology in the Albany Medical College, died at his home after a short illness on July 6, aged 62 years.

Dr. John Augustus Logan of Canton, Ill., a graduate of the Rush Medical College, Chicago, in 1878, and a member of the Illinois State and Fulton County Medical Societies, died suddenly while in consultation in his office on June 26, aged 66 years.

A PRELIMINARY NOTE ON THE EPIDEMIC OF BUBONIC PLAGUE AT SAN JUAN.

By I. GONZÁLEZ MARTÍNEZ, M.D.,

DIRECTOR OF THE BACTERIOLOGICAL LABORATORY OF THE SERVICE OF SANITATION OF PORTO RICO.

On the afternoon of June 15 Dr. Frías communicated confidentially to our Laboratory Assistant Mr. Loubriel that he had seen two cases that showed symptoms that made him suspect bubonic plague. Mr. Loubriel immediately advised Dr. Watson, the acting director of sanitation, as to the confidential information he had received, and this latter made an examination of the patients and ordered the necessary quarantine measures.

On the morning of the 16th the director and chiefs of divisions of the department got together and, realizing the seriousness of the sanitary problem to be solved, decided on the importance and necessity of a correct bacteriological diagnosis. To proceed with more rapidity we divided the work, commissioning Dr. Hernández, assistant bacteriologist of the laboratory, to perform the autopsy of Pedro Colón, one of the cases, who died in less than 60 hours, apparently of a grave septicemia. We took to our charge the delicate work of collecting specimens and making the bacteriological examinations in the case of Miguel Llanos, a patient who had been already isolated in the Quarantine Hospital.

When we began the work, two hours after the meeting, we found Llanos adynamic, with high fever, and an enormous bubo in the left inguinal region. There was no erosion whatever in the corresponding extremity, nor the least lesion on the scrotum or penis. The patient stated that on previous occasions he had had similar attacks with swelling of that group of lymphatic glands, and this made some of the physicians who examined him think that we might be dealing with a filarial adenolymphangitis.

We, who had had the opportunity of seeing several cases of plague in Oporto during the first half of the year 1900, held him as suspicious, and taking all the precautions necessary to avoid disseminating the bacillus hidden in the ganglia, after painting the part with tincture of iodine, we punctured aseptically the ganglion, and aspirated several drops of the ganglionar and periganglionar juices, with which we prepared several smears, inoculated glycerin agar and simple agar test tubes, and injected a guinea-pig.

The post-mortem examination of Cólon, performed by Dr. Hernández and by Dr. Belaval, health officer of San Juan, revealed, according to their report, the characteristic lesions of a grave pneumonia. They prepared smears from the lungs, spleen, and liver, also made cultures in simple agar and glycerine-agar test-tubes and inoculated two guinea-pigs. The microscopical examination of the smears did not throw sufficient light to clear the diagnosis, as the autopsy was made nearly 24 hours after the death of the subject and the bacteria of the cadaveric flora covered almost entirely the microscopic fields. Under such circumstances it was difficult to form a definite opinion, and the case was regarded as negative. However, when on the following day we examined with more care the same smears, we found, mixed with the putrefactive bacteria, and scattered among them, a short thick bacillus, with rounded ends, which was Gram negative and had the polar staining characteristics of *Bacillus pestis.*

In this case the cultures were negative because of the reasons above mentioned, and the experimental inoculation was also unsuccessful, the guinea-pig dying of a rapid septicemia.

But if this case, even though suspicious, had lost, because of the above-mentioned reasons, its diagnostic importance from the bacteriological point of view, in its relations to an official declaration of an epidemic disease, the case of Miguel Llanos offered the best guarantee for a correct solution of the bacteriological diagnosis and the subsequent sanitary problem. The microscopic examination of the smears showed the exclusive presence of a coccobacillus with the following morphological characteristics: a short, thick bacillus, 1½ microns in length by 0.75 to 1 in width, with rounded ends, more deeply stained toward the poles than at the center when subjected to the action of the aniline dyes and specially to the diluted carbol-thionine and carbol-methylene-blue of Kühne. Their mode of taking the stains gives them a "dumbbell" appearance and one is likely to confound them with a diplococcus. Said bacillus grew slowly in the cultures of simple agar and glycerin-agar, the characteristic colonies not being visible to the naked eye until after being exposed to the temperature of the room for 36 hours.

With the object in view of hastening the diagnosis, now that the examination of the smears had made us suspect that the bacterium we were trying to isolate was the *Bacillus pestis* of Yersin, we did not wait for the spontaneous death of the guinea-pig, which already exhibited symptoms of a grave disorder, but killed it and made our examination at once. The anatomopathological lesions of the guinea-pig were those characteristic of the plague: a large sized bubo in the lymphatic gland corresponding to the leg in which it was inoculated; notable infarcts of the spleen and liver, pneumonic foci, very much enlarged suprarenal capsules, considerable increase in volume of both kidneys, a peritoneal exudate, and capillary hemorrhages in the infarcted ganglia and the viscera. We found both in the ganglionar juices, the sanguinolent serosity of the peritoneum, and in the juice from the spleen and liver, the same germ that we had found in Miguel Llanos, in the subcutaneous gelatiniform edema of the guinea-pig, and in the pathological sections of a human bubo. Doubt was now impossible, and we therefore sent to the director of health without further delay a preliminary report of our work.

The official declaration of the existence of such an epidemic, which is one of the three great plagues of humanity and the most fatal of all pestilential diseases, could not and should not be made without having for a base the results of a careful bacteriological examination. Now, this being a work whose technical direction we had assumed wholly, it can be understood that we had to bear the weight of all the responsibility which came with it. We knew that after our report, and using it as a support, sanitary measures would be taken which would cause mental uneasiness in the homes of the city, would greatly interfere with the Island and foreign trade, and would spread a panic all over the island. This would be a serious state of affairs, and it is not strange, therefore, that we felt it necessary to proceed with much caution. There could, however, be no doubt that the bacillus which we had found in our case and later in similar cases,

was none other than the *Bacillus pestis* of Yersin. Among the bacteria pathogenic for man, this is the only one that possesses all the characteristics already described; it is true that the chancroid bacillus (bacillus of Ducrey) simulates it in shape and staining properties and is sometimes found in venereal buboes, but it is, nevertheless, true that said microbe cannot be cultivated in ordinary culture media, nor is it pathogenic to laboratory animals.

The origin of this outbreak is still obscure. We suppose that the plague was introduced from Venezuela, not directly but in an indirect manner, by means of a port which is not in quarantine, without any human epidemic, and the ships from there would not therefore be subjected to "deratisation" in the port of origin or while unloading at San Juan. It is true that the investigations made to determine if there had been any increase in the death rate of rats previous to the explosion of the epidemic have shown that two or three months before any human cases were noted there had been an abnormal death rate among these rodents in several warehouses of the "Marina," possibly because from that date the epizootic had been making ravages among them.

Perhaps the first human cases were unnoticed or were confused with other grave and fatal diseases, due to a lack of careful examination of the patients. This is almost positively so, though not proven. With regard to the epizootic of plague among the rats, we have proven beyond doubt its existence in the *Mus decumanus* and the *Mus rattus*, and the bacteriological examinations which are now being made in the special Plague Laboratory which has been established, will show to what extent the epidemic has invaded them.

It has been said that the cases of plague which have so far occurred have been of a benign type, but this is erroneous, as among the 26 positive cases there were, up to June 29, 17 deaths, which shows a mortality of 65.3 per cent. Of these 17 deaths, 14 occurred at San Juan, one in Arroyo, one in Carolina, and one in Loiza. Of the 14 at San Juan, one was of pneumonic type and another of the septicemic variety.

In a civilized community the gravity of an epidemic cannot be judged by the number of cases. The sanitary organization and the intellectual capacity of the people must be borne in mind; and in this respect the Department of Health of the Island and the inhabitants of San Juan, united by the same idea of defense of the community, have worked with extraordinary activity, heroic energy, and admirable skill. That is the reason why we shall not see repeated in Porto Rico the frightful mortality of India.

San Juan, Porto Rico, June 29, 1912.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER LIBEL CASE—ASYLUMS BOARD—INSURANCE ACT—SLEEPING SICKNESS—HOSPITAL STAFFS PLEDGE—R. A. M. C.'S DINNER.

London, June 21, 1912.

After a trial extending over four days before the Lord Chief Justice and a special jury, an action for libel against Dr. Bashford and the British Medical Association has resulted in damages of £2,000. The suit was brought by Dr. Robert Bell, formerly of Glasgow, who has written a good deal about cancer, which he declares is curable and preventable. His treatment is largely dietary, but he has used thyroid extract, cocaine, salicylate of soda, x-rays, hot air, etc., but places most reliance on atoxyl. He professes to be able to diagnose cancer by examining the blood, and from its indications to eradicate the disease. As a consequence of these views he condemns operations; although he for some years performed them, he said they never cured. He admitted that his statements were in direct contradiction to the teaching of the entire profession. But of course that would not make him a quack. Heterodoxy in medicine is not punishable, but there are methods of appealing to the public practised by quacks, and the profession regards with suspicion the least approach to them.

The libel complained of was written by Dr. Bashford and commented on by an even more caustic remark by the editor of the *Journal*. The publication was in a special cancer number, in May, 1911. That the words applied to Dr. Bell are libelous has been affirmed by the jury. The defence was that the allegations of facts were true and the expressions of opinion fair comment. In his summing up the judge assumed that the jury would find that the article called plaintiff a quack, but he warned them that that would not necessarily mean he had been libeled. He reminded them that the court was not a scientific theater, and what they had to decide was whether there had been a libel or not. If they disbelieved a substantial part of the plaintiff's evidence they should not decide for him. If they believed he told a true story "they should ask themselves whether it was right to describe him, a competent medical man, as a quack because of what he has done or preached. If he exploited the timid or credulous for his own advantage, of course he would be a quack."

Obviously a court of law is not the place to discuss medical theories, and, as the judge pointed out, the one question to decide was whether the severe criticism amounted to a libel. This was urged by plaintiff's counsel because the condemnation of the critics applied the words to Dr. Bell by name. It was admitted that plaintiff's language was quite as strong. He had spoken in a lecture of "serum quackery," and in one of his books said: "Quacks with their serum have been enabled to prey upon the country." When reminded of this, he said he had not libeled an individual. It was the system he spoke of. His own counsel said no one understood cancer, but he contradicted that and said he comprehended it. He had written that surgical operations almost amounted to a crime. He had given them up, as they were always unsuccessful. His teaching contradicted the whole profession. He adhered to the statement he made in the *Daily Mail* that cancer was not only curable but easily preventable. Among the curious incidents of this four-day trial was the challenge about blood examinations. Dr. Bell declared he could diagnose cancer by them. Defendant produced specimens. He pronounced one to be cancerous which had been taken from a healthy man standing near him, and, in fact, failed with all.

When asked about the cases of operations that did not recur, he said they were tumors, not cancerous, apparently not realizing that the same explanation might be applied to his own cases. Many strictly medical points were brought forward at this trial, although the judge had distinctly stated that the only question for the jury was whether the criticism amounted to libel. The jury found that

it did, and gave heavy damages, but there will probably be an appeal.

The Metropolitan Asylums Board employs 5,300 persons who come under the Insurance Act. About 1,800 are nurses who "contract out" under the Poor Law Acts. The Board will, therefore, apply for the certificate of exemption for such employees. With reference to the requirements of the act for sanatorium treatment the General Purposes Committee has been requested to report whether the Board is in a position to undertake the provision of the sanatorium accommodation for the county of London.

The Commission on Sleeping Sickness, which went to Africa about a year ago to inquire into the origin of the disease in regions where the *Glossina palpalis* was not known, is now at work in Rhodesia. Reports have come to hand which declare that the *Glossina morsitans* is the carrier. Not only so, but Drs. May and Kinghorn assert that the *Glossina morsitans* has been proved to convey the disease both in the ordinary conditions of the country and experimentally. Further, it is said that some animals may convey the *Glossina* without themselves suffering from it. If this should be fully established it will certainly explain many outbreaks which have heretofore been inexplicable. It is of real significance that the *Glossina palpalis* and the *Glossina morsitans* are both carriers because, while the former is only met with in clearly defined, narrow limits by the watersides of Africa, the latter is found throughout the continent. Northern Rhodesia seems more free from the flies than many parts. No cases of sleeping sickness have been reported there among the whites for a long time.

Many unexpected occurrences result from the Insurance Act. The Prudential Assurance Company arranged a scheme to relieve employers of all trouble and expense in regard to the stamping and custody of cards, but the Commission considers no approved society or other body should enter into such arrangement. So the offer is withdrawn and the Commissioners are not complimented by employers or others.

The medical and surgical staffs of the hospitals met at the Royal Society of Medicine, and by a great majority decided to support the pledge of the British Medical Association.

Dr. Fordyce of Cambridge, who was elected by the County Council as medical representative under the act, has declined acceptance until the six points are agreed to.

The Commission has issued a circular conceding to large employers the privilege of stamping quarterly instead of weekly, but the permission is hedged by so many conditions that it looks as if the annoyance and burden of this stamping would be in no way diminished.

It seems early to be speculating on what may be the proceedings of the British Association next September. Yet the officials of this organization for promoting science have made considerable progress with the program. The meeting is to be at Dundee, and Professor Schäfer is to preside. It is whispered that his address will probably trace the progress of microscopic anatomy during the past generation. Professor Keeble's address in the Botany Section will deal with genetics and physiological research. A joint discussion of this section and that of zoology on the origin of life is to be opened by Professor Minchin. The Physiological Section, president Dr. Leonard Hill, is expected to be unusually attractive. A discussion on mind and body is arranged in which Sir T. S. Clouston and Drs. Haldane and Watt have already agreed to take part. Among papers to be read are those by Drs. Dawson, Mayo, A. Waller, and Rentoul.

In the Chemistry Section Professor Senier will preside and in his address review the foundation and progress of the organic branch. Joint meetings are also expected with the sections of physics and botany. The University of St. Andrews will be represented as to the research on sugars, in which its chemical department has long been engaged.

Surgeon-General Sir W. L. Gubbins, Director-General, took the chair at the annual dinner of the R. A. M. C. on Monday, at which 228 past and present officers attended.

OUR LETTER FROM THE PHILIPPINES.

(From our Regular Correspondent.)

WATER-SUPPLIES—LOWERED DEATH RATE DUE TO PURER WATER—LARGE HYDROCELE—SALVARSAN AS A PACIFIER—SANITATION AMONG THE SAVAGES—CHOLERA—THREATENED PLAGUE—PERSONAL.

MANILA, May 17, 1912.

THE campaign for better water supplies in the Philippines, which has been so persistently waged since American occupation, is now beginning to bear fruit at a rapid rate. When Spain relinquished authority over the Philippines, with the exception of the water system in the city of Manila there was practically no water supply installation in the entire archipelago. Water was obtained either from shallow surface wells, or simply dipped from the rivers as they flowed past the various towns. The question as to whether the water was really safe and potable, or of the convenience of having it delivered by a system of pipes, seems never to have been seriously gone into. For a number of years after American occupation the apathy of the Filipino people toward better water seemed almost impossible to overcome, but by a campaign of education persistently carried on, Filipino officials were gradually interested in the project, and through them, the masses of the Filipino people, with the result that at present a good water for domestic purposes is one of the leading public questions of the day in the islands, and forms one of the planks in the platforms of the candidates of almost all Filipinos for public office.

In 1906 the first artesian well was bored in the islands, and now they may be numbered by the hundreds, and a decreasing mortality curve has followed in their wake wherever they have been installed and the water extensively used. As experience was gained with artesian wells, it was found that the conformation of many sections of the islands was not favorable for artesian wells; therefore, the plan of collecting water from uninhabited water-sheds, damming it up, and distributing it, through reservoirs and pipes, had to be considered. There are at least 50 towns in the islands, now, that are considering the installation of a water system of the latter kind. The health officials have been very reluctant to encourage the use of surface waters, even though the water came from an uninhabited water-shed, because the question as to whether the amebæ which are found in all surface waters that are not thermal or strictly chemical, are pathogenic or non-pathogenic has not yet been satisfactorily determined. But, as the studies in this matter proceed, it seems more and more likely that amebæ are of two kinds: First,

the harmless variety, which is found in all surface waters, and second, the pathogenic variety, which are only found in water, on vegetables, or other substances when they have been directly or indirectly placed there through the means of stools from cases of dysentery. This accords very closely with the experience which has been had during the past few years, in Panama, as a result of which, water supplies on the Isthmus are now being everywhere installed without regard to the ordinary surface amebæ.

The installation of water supplies has lately received considerable additional impetus by the drought which has occurred in the Philippines during the past seven months. According to the records of the Weather Bureau, this drought has been the most severe in thirty years. In many places, all other sources of water supply with the exception of artesian wells, were completely exhausted, and this has served as a practical demonstration to the people of the desirability and necessity for artesian wells.

The extraordinary development in connection with the installation of better water supplies in the Philippines is an excellent concrete example of what may be accomplished when officials of all classes work harmoniously together for the purpose of attaining an object. Everyone, from the Governor-General to the lowest paid official, took occasion, when opportunity offered, to encourage the use of better water, and the constantly decreasing death rate is the monument to their efforts.

At the small emergency hospital which exists at Surigao, in the province of that name in Mindanao, an unusually large hydrocele came to notice a short time ago in the person of Servando Acle, age 35, a resident of Surigao, who had suffered from hydrocele for the past seven years. Upon the sacs being punctured, 4 liters of fluid were extracted, three coming from the right sac, and one liter from the left sac.

The progress which has been made in sanitation among the wild tribes in the Philippines has indeed been most noteworthy. Where, a few years ago, wild, head-hunting savages roamed at will and indulged in their murderous practices on every hand, there now exist modern hospitals where many of these same savages of a few years ago now apply for treatment, and the doctor and the nurse go about the country in security and safety administering to their various physical ailments. Recently, rapid progress has been made in promoting friendly relations with the Igorrotes, largely through the use of salvarsan. The Igorrotes suffer very frequently from yaws, and as one intravenous injection of this drug usually cures them and without undergoing a prolonged stay in the hospital, the remedy has been very popular and they have attributed marvelous powers to the treatment of the white man, and through this are coming very rapidly under his control.

In many of the towns that are now occupied by Filipinos and wild men, much better sanitation prevails than is the case in the average Christian town in the Philippines. In towns like Bontoc and Cervantes, for instance, the pail system is used, and there is a daily collection of garbage as well as of pails. Streets are swept daily, modern market buildings have been provided, yards have a neat and tidy appearance, etc. Owing to the friendly relations which have been established it has been possible to send groups of vaccinators among these people, and during the past six months over 65,000 of them have been vaccinated against smallpox. In the mountain province there has been opened at Bontoc a modern hospital with thirty beds capacity, and a dispensary and emergency hospital has been opened in Quiangan, Banaue, Cervantes, Tuao, and Tagudin, which are five of the capitals of the subprovinces which make up the Mountain Province, at Bontoc and Baquit, the two remaining capitals of sub-provinces, there are modern hospitals. The Mountain Province now has two doctors assigned to it and each sub-province has a sanitary inspector in addition to the aid which is rendered by the medical department of the constabulary.

Cholera has been reported from time to time during the past month in various provinces of the Philippines, but investigations of this matter have, so far, always resulted in finding that the reports were false. Bacillary dysentery, however, does exist in many portions of the Philippines and has been the cause of considerable mortality during the present year.

The quarantine restrictions which were imposed against Hongkong on account of the cases of pneumonic plague which were recently encountered on ships from that port have, so far, apparently been successful in preventing additional cases being brought to Manila.

Dr. P. Elkington of Brisbane, Australia, the chief medical officer for Australia, is due to arrive in Manila on May 27 for an extended stay in the Philippines for the purpose of study and observation.

Progress of Medical Science.

4. A Study of Erythrocythemia and Report of a Case, with Autopsy. A. L. Hamilton and M. E. Morse.
5. A New Mastoid Retractor. P. Hammond.

2. **The Technique of Transfusion.**—E. H. Risley and F. C. Irving believe that among the various mechanical metal devices for effecting transfusion the Elsberg cannula is the best. Among the other devices that have been invented for this purpose are the following: (1) The modified Crile cannulæ of Buerger or Burnheim, with the long handle for convenience in handling and the three equidistant prongs over which the vessel walls can be hooked and held; (2) the dog's carotid proposed by Frank, which gives great length of connecting surface and room in which to work, and which is entirely feasible but not possible to have on hand at a minute's notice without considerable previous preparations; (3) the modified Crile cannula of Hepburn, which has a perforated plate attached to the cannula, through which the stay sutures are threaded and securely tied and adjusted; (4) the male and female hemicylinders with spring arms and fixation posts of Janeway, which insure the proper apposition of intima to intima and should be easy of application; (5) the similar but less easily applied cannulæ of Soresi. All these devices have several definite objections: They are sterilized with difficulty and require special skill in manipulation. They must be made by skilled instrument workers at considerable cost and cannot be quickly and easily adjusted. The authors believe that the safest, simplest, and most reliable method of transfusion is that effected with the aid of glass tubes. A nest of tubes can be blown in a very short time and can be easily lined and coated

with a mixture consisting of paraffine 2 parts, petrolatum 2 parts, and stearin 1 part. The use of these tubes was first advocated by Brewer and Leggett, and later by Vincent. The glass bulb of David and Curtis is also extremely simple and safe and affords accurate measurement of the blood transfused. It is possible to do transfusion without cannulæ or clamps or any other mechanical aids, provided enough length of artery and vein is dissected out.

3. **Operability of Cerebral Endothelioma.**—G. L. Walton and J. Homans state that the form of a new growth of the brain offering the best chance for successful removal and perfect recovery is the endothelioma. Unfortunately, however, the very factors that contribute to this result render this form of tumor the most elusive from a diagnostic point of view; these factors are lack of pressure symptoms and lack of symptoms pointing to disintegration of brain tissue. It is particularly important, then, that the general practitioner as well as the surgeon and the neurologist become familiar with this tumor and bear it in mind in case of continuous and increasing cerebral symptoms, such as epileptiform attacks, even though the eyegrounds and intellect be clear, the sight and other functions of the brain unimpaired, headache and vomiting slight or absent, and the general condition good. These tumors spring from the endothelioma of the dura and gradually impinge upon and displace brain substance without destroying it, excepting very superficially in certain cases, after considerable growth, the brain being in such cases softened and sometimes adherent to the tumor at the periphery. These growths are not malignant and have no tendency to local recurrence, or metastasis. They spring from the dura, to which they are closely but not extensively adherent, and gradually increase as solid growths, sometimes with projecting knuckles, finally reaching a diameter of several inches, being then still well defined but not encapsulated.

4. **Erythrocythemia.**—A. L. Hamilton states that Weber defines this as "a disease, or at least symptom-group, characterized by persistent and absolute polycythemia (increase in the number of red corpuscles) due to excessive erythroblastic activity of the bone marrow without the presence of any recognized, or at all events sufficient, exciting cause; it is also characterized by persistent increase in the viscosity and total volume of the blood, and usually by a cyanotic appearance of the patient and by enlargement of the spleen." Some of the cases reported have not been cyanotic. The patients complain of weakness, pain in various parts of the body (especially in the head), vertigo, and constipation. Hemorrhage is not uncommon, especially cerebral hemorrhage. Chronic cyanosis is, of course, a common condition, occurring in various diseases, such as organic disease of the heart, especially of the congenital type; diseases of the lungs, notably emphysema, and occasionally after the long-continued use of coal-tar products (antipyrin or acetanilid), owing to the presence of methemoglobin. The count of red cells in the peripheral blood is increased in cardiac and pulmonary diseases causing cyanosis, because the cells are crowded at the surface of the body, but there is no total increase of cells, merely a change of distribution. Such cases are distinguished from polycythemia by the presence of a clear cause for peripheral stasis. The points of special interest in a case of polycythemia reported by the author are: (1) The very marked apparent improvement under treatment by exposure to the *x*-rays; (2) the decrease of the liver from very great size to about normal, apparently due to improvement, but really due to degeneration; (3) the varicosities of the esophageal veins, common in alcoholic cirrhosis of the liver; and (4) the extraordinary and fatal hemorrhage, due to rupture of the esophageal vein.

7. The Care of the Health during the Menstrual Period and the Menopause. A. Parry.
8. A Theory of the Origin of Disease. C. O. Linder.

1. **Tuberculous Infection, Eugenics and the Cost of Tuberculosis.**—S. A. Knopf notes that about two million dollars are spent annually in the city of New York in the fight against tuberculosis. Besides pleading for the extension of the various medical and sociological measures that have been suggested as means of combating this disease, the author advocates the performance of vasectomy for all tuberculous male patients who will voluntarily submit to this operation, and if the patient is acutely tuberculous and if he insists upon marrying, the author would make this operation obligatory. In females similarly situated the operation of ligation of the Fallopian tubes is advised.

2. **Salvarsan and the Eye.**—R. G. Reese concludes that salvarsan is a powerful symptomatic remedy for the treatment of luetic eye lesions. It merits attention, especially in combination with mercury and iodine. Its action is more rapid than that of mercury, but it should not replace that valuable remedy, except in selected cases. It should be given intravenously for quick action and for the comfort of the patient. It should not be given in simple, spinal, noninflammatory atrophy of the optic nerve.

3. **Neosalvarsan.**—A. G. Rytina states that the advantages which Ehrlich claims for this drug over salvarsan are the following properties: High solubility, neutral reaction, low toxicity, equal if not greater effectivity than salvarsan, and the fact that reaction symptoms such as diarrhea and vomiting do not occur even after the administration of large doses. The preparation which bears the name of neosalvarsan is a true derivative of salvarsan. It has the laboratory number 914, which indicates the labor expended upon it. According to Ehrlich, it arises through a condensation of sodium formaldehydesulphoxylate [CH_2 (OH) O—SO—Na] with salvarsan. From his study and brief experience the author feels justified in drawing the following conclusions: (1) Neosalvarsan is a highly soluble and absolutely neutral compound; (2) the clinical results are just as effective, if not more so, than those of salvarsan; (3) injections are free from the severe constitutional and local reactive phenomena that often follow injections of salvarsan; (4) on account of the neutral reaction, the preparation lends itself well to intramuscular injection, thereby allowing a more prolonged and protracted action.

5. **Alopecia Areata.**—P. E. Bechet believes that the so-called contagious variety of this disease is not a true alopecia areata, but a separate disease due to a specific bacillus. True alopecia areata is a trophoneurosis and is not contagious. For instance, the returning hair in alopecia areata is almost always white, thin, and slender. The returning hair from any parasitic affection of the scalp is always normal as to color and consistence. Alopecia areata is sometimes associated with other conditions, neurotic in character, such as leucoderma. Eddowes, quoted by Stelwagon, reports a case of alopecia areata occurring on an area of leucoderma. Kingsbury reported three cases of total alopecia areata which showed errors of refraction coexisting with ocular muscular insufficiency. Kingsbury thought that total alopecia areata was due to a neurosis and that eye strain might be an etiological factor. There are reported in the literature many cases in which

this dermatosis occurred after sudden nervous shock, from grief, fright, accidents, etc.

1. Aseptic Access to the Pituitary Body.—By L. L. McArthur. (See MEDICAL RECORD, June 29, 1912, page 1245.)

2. Symptoms of Colonic Intoxication.—By J. F. Binnie. (See MEDICAL RECORD, June 29, 1912, page 1248.)

3. Diffuse Dilatation of the Esophagus and Cardiospasm.—By H. S. Plummer. (See MEDICAL RECORD, June 29, 1912, page 1246.)

4. Nervous Symptoms Following Sunstroke.—T. H. Weisenburg states that during the summer of 1911, because of the excessive heat there were more than the usual number of cases of heat exhaustion in the city of Philadelphia. Two of the large number of cases seen by him are reported because of their unusual character. The first was that of a patient in whom a severe sunstroke was followed by multiple nervous lesions producing acute cerebellar ataxia, loss of speech, and spastic symptoms, an unusual combination. The second was that of a cook in whom, because of overheating, there occurred muscular spasms. These spasms are the commonest manifestation of heat intoxication. The interesting feature was that he had an old poliomyelitis of one leg. In spite of this the muscular spasms were just as marked in the palsied limb as elsewhere, this being an interesting contribution to the theory that the spasms are produced by a degenerative process in the muscles and not by a lesion of the nervous system. Although the literature of nervous symptoms following heat intoxication or exhaustion is not very large, yet a great variety of symptoms have been described. Besides the usual rise of temperature, headache, and sometimes coma, there have been quite a number of cases of motor lesions which have been either hemiplegic or paraplegic, and rarely of acute ataxia and disturbance of speech. Curiously enough the author has not found a single instance of such lesions producing sensory disturbances, although there is no reason why these should not occur.

5. Intestinal Implantation of Bacillus Lactis Bulgaricus.—By R. O. Clock. (See MEDICAL RECORD, Vol. 81, page 737.)

6. Sterilization of Defectives.—G. L. Orton states that a bill was passed at the session of 1910-11 of the New Jersey Legislature, and signed by the Governor, empowering the latter to appoint a commission whose duty it should be to sit and act on all cases recommended by the heads of the various institutions, the persons having the right to appeal to the court to show why the operation should not be performed. The law permits and in fact specifies the operation to be performed; namely, orchectomy in cases of rapists, and vasectomy in case of all other defectives. The operation of vasectomy is a very valuable one in these cases and is performed by simply ligating the vas deferens and incising the same. It can be done under local or general anesthesia. It has been performed on several hundred cases in the Indiana State Reformatory with avowed success, and while it absolutely prevents procreation it does not destroy sexual desire or ability for coition.

8. Uncommon Forms of Toxic Dermatitis.—J. Zeisler refers to the occasional irritating effect on the skin of veronal. He reports the case of an individual in whom twelve to eighteen hours after taking five to eight grains of veronal there would be noticed a marked itching on the glans and prepuce. On local inspection a number of round reddish patches would be observed which in the course of a day or two would become bright red, tense, somewhat swollen, and gradually show even a serous exudation. This highly inflammatory state, accompanied by almost unbearable itching, would persist for a number of days before superficial crusting and final desquamation would terminate the process, about eight or ten days after its onset. Another unusual form of dermatitis is that known as primrose dermatitis. During the past two years a number of cases of this affection, probably not less than twenty-five, occurred in the author's practice. In all, the history of severe itching and a localized dermatitis, affecting mainly the hands and the face, formed the striking feature. With few exceptions all were women belonging to the better class. A few were engaged in floral establishments. The local features consisted in the well-known phenomena of ordinary dermatitis, ranging from mild erythema and occasional vesiculation to crusting, fissuring and swelling, associated with itching and burning. In the last few years quite a number of observations of persistent dermatitis have come to the author's notice which he could easily trace to their peculiar causation. Most of the sufferers were women above middle age. One only was a man of about sixty. These people complained of considerable itching and burning of the face, which showed more or less sharply circumscribed redness, with superficial crusting, often involving the ears, but marginated against the hair line and only occasionally involving the hands in the form of a few patches. The eyelids suffer particularly, are usually swollen somewhat, and show superficial transverse rhagades. The patients are otherwise in perfect health and know of their own knowledge no cause for their disfiguring dermatosis. These cases have usually been treated for long periods as chronic eczemas. A close observer will quickly notice the unnatural dead color of the hair, which contrasts markedly with the grayness of the hair close to the skull. These patients do not deny the use of hair dyes.

12. Hexamethylenamine in Affection of the Upper Respiratory Tract.—A. A. Eisenberg concludes that hexamethylenamine is a valuable remedy in the treatment of the inflammatory conditions of the upper respiratory tract. It must be given in doses large enough to secure its full physiological effects. No untoward symptoms were observed while given in fairly large doses (up to 30 grains daily). It seems to prevent possible complications of acute rhinitis, such as bronchitis and sinusitis.

5. A Case of Color Blindness. F. W. Edridge-Green.
6. Two Cases of Pneumococcal Vulvovaginitis in Children. H. Chapple.

1. Moot Points in the Pathology and Clinical History of Pneumonia.—P. Kidd states that Sutherland, as the result of observations made in children suffering from pneumonia, has referred the respiratory and cardiac symptoms of uncomplicated early pneumonia to toxemic dis-

turbances of the respiratory and cardiac centers in the medulla. The examination of sputum is an unsatisfactory method of detecting organisms present in the lungs. Pneumococci may be absent in cases of pneumonia and may be present in cases of bronchitis. As regards physical signs, it is noted that a localized deficiency of the breath sounds is a commoner and more valuable sign of commencing pneumonia than the crepitant râle of Laennec or the fine hair crepitation. The latter may be confounded with the fine crepitation of edema, and is often not heard at all in cases carefully watched from the first appearance of physical signs. According to Gibson, a blood pressure appreciably below the normal in pneumonia is invariably of evil omen, and any considerable fall bodes disaster. It is common to find edema of the lungs and mediastinal tissues in fatal cases of pneumonia, both probably in many instances of inflammatory origin. But cutaneous generalized edema can hardly be regarded in the same light, and may be a toxic effect of the pneumococcus. The records of necropsies at the London Hospital show that obsolete tuberculous nodules are often found in the lungs in cases of lobar pneumonia. But lobar pneumonia complicating declared and progressive tuberculosis of the lungs is exceedingly rare. Acute lobar pneumonia complicating rheumatic fever is very uncommon. It seems to be the fact that the pneumonia of influenza is of two kinds: (1) True influenzal pneumonia, the result of the influenza bacillus, which is always bronchopneumonic; (2) lobar pneumonia, which is probably always pneumococcal. The first may arise at any stage; the latter generally appears rather as a sequel than as a substantive part of the influenza, and is to be regarded as a secondary infection. Pneumonia terminating in organization seems to fall into two groups: (1) Progressive febrile cases, with or without a temporary remission of fever, ending fatally in a few weeks or months. Pulmonary abscesses, gangrene, and other complications may arise. (2) Cases in which the fever declines by lysis, delayed resolution being succeeded by gradual fibrosis and recovery.

3. **Ganglion Neuroma of the Mesentery.**—H. Macnaughton Jones reports a case of this rare condition in a girl aged eighteen years, in whom the growth was first discovered at the age of five years. The mass appeared to be of the size of a large orange, situated below the umbilicus at the left side and covered by the rectus muscle. The only symptoms were nausea and constipation. By a double oblique incision, which included a portion of the rectus, the capsule of the tumor was exposed. It was covered by omentum and partly by bowel. There were some adhesions of the omentum and the bowel which were easily separated, but then it was found that the mass was embedded in the mesentery, between the layers of which it lay. Its firm mesenteric attachment to the left side of the vertebral column was hidden from view and extended for some nine inches. A profuse hemorrhage attended the removal of the tumor. The greater part of the mass consisted of a firm tissue, which was composed of bundles of nerve fibers. The fibers were almost all myelinated. They had a sheath of Henle which varied in thickness, but which was usually delicate. This tissue also contained groups of encapsulated ganglion cells; the nerve fibres surrounding these cells had a very delicate sheath. The ganglion cells were almost all degenerate; some were necrosed and impregnated by calcium. The capsule of the tumor was formed by similar bundles of nerves in which the collagenous sheath was thickened; it was not formed by indifferent fibrous tissue. This firm portion of the mass had the structure of a simple "neuroma ganglionare" or "gangliocellulare."

4. **Dilatation of the Heart.**—H. Davy states that the heart may be invaded by the specific organisms in rheumatic fever, pneumonia, typhoid fever, diphtheria, erysipelas, influenza, and the various septic infections, and that the results of such invasion are shown in the occurrence of endocarditis, myocarditis, and pericarditis. In these cases the tonicity of the poisoned heart muscle fails and thus dilatation takes place. There are many other conditions in which the heart is poisoned by toxins generated in the patient's body. The author has published a series of cases showing that toxins generated from microorganisms in decayed teeth act in this way. In one of these a vaccine made from the bacillus pyocyaneus found in a decayed tooth was actually discovered to benefit greatly the condition of the patient's heart, which had on several occasions been found to be dilated; and in several other cases various microorganisms found in decayed teeth had been associated with heart weakness and probably degeneration of the heart muscle. This poisoning of heart muscle by toxins formed within the patient's body opens up a large field for investigation. The action of toxins in cases of chronic constipation and intestinal stasis is already being recognized, and their action on the heart and other organs of the body is beginning to be known. It is possible that it may be found that other organs of the body may be invaded by microorganisms which produce toxins that affect the heart muscle, but at present this has not been proved.

5. **Color Blindness.**—See page 68.

6. **Pneumococcal Vulvovaginitis in Children.**—H. Chapple reports two cases of this condition, which were clinically indistinguishable from other cases of vulvovaginitis. Their exact nature was to be recognized only by bacteriological examination. The following treatment was employed: For the first few days the child was kept at rest and the parts were bathed at frequent intervals with a warm lotion. An autogenous vaccine of 5,000,000 pneumococci was given. The acute nature of the inflammatory process rapidly subsided, and then warm vaginal douches of zinc permanganate were given under low pressure. Had the patient been an adult it would have been wiser first to plug carefully the orifice of the external os with a suitable tampon in order to prevent the possible ascent of organisms during the douching process. This was not feasible in this child. The inflammatory process did not spread further than the vagina, and in ten days the discharge was almost gone, but pneumococci were still present in the vagina. Consequently another vaccine of 5,000,000 was given, and the local treatment was continued. The condition rapidly cleared up, requiring only four vaccines in all, and the patient got quite well, the vaginal swab showing no pneumococci present. Recent methods have shown that pneumococcal peritonitis is not an uncommon affection in girls. To those who hold that the path of infection may be an ascending one by the Fallopian tubes these cases will be of interest. The pneumococcus is present in the vagina more frequently than is supposed. The possibility of such an ascent affords an additional reason for being anxious to detect the exact nature of a discharge at the earliest possible moment, and to rid the patient of her infection by the most rapid possible means.

6. The Rapid Cure of Amebic Dysentery and Hepatitis by Hypodermic Injection of oluble alts of Emetine. L. Rogers.

1. **Colic.**—G. Rankin states that the word "colic" was originally meant to be descriptive of a sudden, acute, paroxysmal pain produced by some abnormal condition of the colon. A wider significance is now attached to the term, which has come popularly to connote pain of this

description occurring anywhere throughout the body, when it is dependent upon either irregular active contraction or excessive passive dilatation of involuntary muscular fibre. The most homely example of colic is that due to muscular spasm of the intestinal walls resulting from the presence of irritating food. Another striking variety is that produced by gallstones impacted in the cystic or in the common duct. Comparable with biliary colic and announced by the same sudden series of symptoms—rigors, pain, and vomiting—is ureteral colic. The author enumerates and describes the other following forms of colic: that due to lead poisoning; the pain caused by neurotic dyspepsia; colic due to impaction of a pancreatic calculus in Wirsung's duct; appendicular colic; the colic associated with mucous colitis; the pain caused by movable kidney; the colicky pain caused by embolism or thrombosis of the mesenteric vessels; "angina abdominis," comparable with the spasm of the vessels seen in ordinary migraine; the colic frequently occurring in the terminal stage of diabetes; and the pain due to aneurysm of the abdominal aorta, malignant disease of one of the abdominal organs or of the retroperitoneal glands, hysteria, and the visceral crises of locomotor ataxia. In women, colic may result from disorders of the bladder, uterus, tubes, and ovaries.

2. **Surgical Significance of Enterospasm.**—J. Swain states that pain, vomiting, and collapse constitute the cardinal symptoms of most acute abdominal crises. Every surgeon of experience occasionally meets with cases in which the severity of these symptoms is strongly suggestive of intestinal obstruction or some other important abdominal lesion; but on opening the abdomen nothing abnormal is found, the symptoms cease, and the patient soon recovers. Some of these cases are of purely functional origin, those of an acute type being probably due to painful contraction of the small intestines—enterospasm—and those of a chronic type being associated with pain of the nature of "colic" in the large gut. That enterospasm is capable of simulating an acute abdominal crisis is suggested by the fact that recovery follows operation when the pain and vomiting are sufficiently severe to necessitate a celiotomy, which is performed in some cases because of the impossibility of being certain that the symptoms are merely due to a functional intestinal disturbance. Moreover, in some cases the intestines are actually to be seen markedly contracted at the time of opening the abdomen. The seat of the greatest intensity of the pain generally appears to be referred to the neighborhood of the umbilicus, there is often a history of irregular action of the bowels, and the abdomen is frequently retracted. In this last respect the condition resembles the early stage of most acute abdominal lesions, and when associated with considerable superficial tenderness it is extremely difficult to exclude some forms of peritonitis. Nevertheless, in many of these cases the general condition of the patient does not suggest a serious mischief, and it is not uncommon to find that the diaphragm acts freely, so that a deep breath may be drawn without adding to the patient's suffering. In doubtful cases of severe intestinal trouble a gradually increasing distention in association with pain and vomiting may be regarded as a clear indication for operation; but it is not often desirable to wait for this as a means of diagnosis, and it is far wiser to run the risk of operating unnecessarily in a case of enterospasm than to neglect to interfere in an obscure case of acute intestinal obstruction or other morbid abdominal condition which may be amenable to surgical procedures. The exclusion of a malignant neoplasm is of the greatest importance.

3. **Salvarsan in Pernicious Anemia.**—B. Bramwell states that in March, 1911, he reported two cases of pernicious anemia in which great improvement resulted from the administration of salvarsan. He now records the further progress of these cases—they have remained well without any further treatment—and the results in five other cases treated in the same way. Since the author commenced to treat cases of pernicious anemia with arsenic in the year 1875 he has had a large experience with the disease; the impression which has been made upon his mind by the results of the salvarsan treatment in the seven cases is, on the whole, very favorable. He believes that salvarsan will probably be found to be a more efficient remedy than arsenic given by the mouth, and indeed than any form of treatment which has as yet been employed in this very grave and intractable disease.

6. **Emetine in Treatment of Amebic Dysentery.**—L. Rogers states that the principal cause of the vicissitudes of ipecacuanha is the production of very disagreeable and exhausting nausea and vomiting by the large doses which are essential to obtaining its full curative effects. This serious drawback is only partially overcome by the present methods of giving the drug in salol or keratin coated pills, and the use of opium, chloral hydrate, or tannic acid to check vomiting. Last year Vedder showed that emetine, the principal alkaloid of ipecacuanha, has the power in high dilutions of destroying amebæ in broth cultures, although it is not clear that this was a pathogenic form, which most recent authorities believe has not yet been cultivated. The author has, therefore, tested the effect of the soluble emetine hydrochloride on *Ameba histolytica* in dysenteric stools. He has found that, on placing a piece of mucus containing numerous active amebæ in normal saline solutions of this salt, the pathogenic organism is immediately killed and materially altered in its microscopical appearances by a 1 in 10,000 solution, while after a few minutes they are rendered inactive, and apparently killed by as weak a solution as 1 in 100,000. He has therefore decided to try if this powerful alkaloid can be safely administered hypodermically in the treatment of amebic disease, and has obtained striking results in a few patients.

Etiological Significance of Psychic Insults in Affections of the Blood Glands.—Münzer first refers to diabetes, Graves' dsease, myxedema, and acromegaly as a disease group due to disorders of the blood glands. To go no further than this grouping, however, means nothing at all in connection with the intimate nature of these affections. What factors bring about these disturbances? Are they common for the entire group? This is hardly probable. All possess a notable hereditary element, but this refers only to the individual diseases. We do not find group heredity. The great causative factors of chronic disease in general may be noted in most of these affections, and the general factor in etiology stands out with prominence. This is psychic insult which may be brought into relationship with all or nearly all of the blood gland diseases. These insults naturally comprise fear and worry, fright, grief, vexation, despair, or from a more objective viewpoint domestic and business troubles. A factor like psychic insult may readily be understood as having the power to affect several blood glands at once, although such is the interdependence of these structures that a serious affection of one gland might involve others. Again the psychic trauma would not manifest itself on the blood glands alone, but could affect other functions, not omitting of course the brain itself. Hence despite the somatic character of the affection the germ of the latter may be in the brain, as in any other psychogenous malady. The author is more dubious about the hypophysis than any of the other blood glands, in regard to a psychogenous factor. The latter can readily be established in connection

with affections of the thyroid, pancreas and adrenals. The anatomical relations of the hypophysis associate its physical anomalies with central nervous symptoms, but a set of phenomena due purely to disturbed innervation of an anatomically intact structure is not yet known to exist although Pel has reported cases of acromegaly due apparently to psychic trauma.

Early Diagnosis of Primary Lung Tumors and the Possibility of Operative Removal.—Ephraim states that radiography has not added anything to our diagnostic resources in this field, for the growth must often be quite far advanced before its presence can be detected in this manner. Bronchoscopy also has a limited field, and it is sometimes possible to excise a bit of tumor for diagnostic purposes when one projects into a brochus. On account of the tendency of primary tumors to appear in or near the bronchi a combination of resources sometimes enables us to make the correct diagnosis when the first subjective symptoms cause the patient to seek medical aid. These symptoms comprise dyspnea and hemoptysis, cough and stridor; and auscultation and percussion can be depended on to furnish data, aided of course with the sputum investigation. The author reports a number of cases of malignant disease in which a correct diagnosis was promptly made. Naturally for such cases not much can be done as a rule. The author, however, succeeded in extirpating one bronchial cancer by the natural route and cauterizing the base and the patient is still free from disease after two and a half years. It is also worth while to *x*-ray these growths with the hope at least of prolonging life.

Münchener medizinische Wochenschrift.

June 18, 1912.

Duodenal Ulcer.—Hans Kehr asks why it is that Mayo and Moynihan diagnosticate and operate on so many cases of duodenal ulcer, while in Germany the converse is the case. Does this contrast redound in any way against German surgery? The author has been in the United States and as far as diagnosis is concerned found no superiority there over German colleagues. The latter, however, are more conservative when it comes to laying down operative indications; while the American public appear to be far better disposed to trust themselves to the knife than are the Germans. There is also perhaps a disposition on the part of some American and English surgeons to operate for a record or as a cure-all. They do not adhere to the maxim that it is better to be a physician first and an exciser of ulcers or appendices afterwards. The author regards it as a higher art to forego operation in select cases than to operate broadcast. Despite the author's record as a gallstone operator he rather prides himself more on what he forbore to do than on his record. Full credit is given to the Mayos for their immense activities and low mortality. The gospel of early intervention is preached and practised by them to the full. But the great reputation, the strong personality, the belief in operating, on the part of the surgeons, and the willingness of the patients to submit to operation, are all powerful factors in determining the amount and character of the work. Perhaps the same aggregate of good could be attained with far less surgery.

Endothelioma of the Nasal Septum.—Trautmann believes these growths to be much more common that statistics show, because a correct microscopic diagnosis of so little known a tumor can seldom be made, the material being buried in the literature of carcinoma and sarcoma in this as in other localities. The author can find but four published cases under this head and adds a fifth. Clincally the growth was a fibrous polyp with nothing to suggest malignancy. The diagnosis of the university pathologist was endothelioma undergoing myxomatous degeneration. Without special care in diagnosis such a growth would doubtless impose itself as a myxosarcoma. The growth was excised with a part of the septum and the prognosis for recurrence guarded.

De Quervain's Disease.—Flörcken, while not exactly naming a recently described affection for its reporter, described a case under the designation "stenotic tendovaginitis of the processus styloideus radii (de Quervain)." It is not quite six months since this affection was apparently first described by de Quervain under that designation. It is quite different from a condition secondary to habitual subluxation, also recently described and for the first time by Burk. In one of the author's cases the patient was a young woman who could not account for the lesion unless it could be attributed to cycling. The thumb of the affected side was crippled, extensions being very painful. The radiograms showed no bone lesions. There was tenderness over the affected tendons. Diagnosis was confirmed by operative incision into the sheaths of the abductor longus pollicis and extensor brevis pollicis, the tendons being then freed from the sheath.

Deutsche medizinische Wochenschrift

June 20, 1912.

Treatment of Climacteric Disturbances with X-Rays.—Runge states that the use of radiography is constantly broadening in gynecology. It is now used in myomata, climacteric hemorrhages, dysmenorrhea, pruritis, and kraurosis vulvæ. At the present time no less than 137 patients are receiving the *x*-ray treatment for these affections in the gynecological clinic of Charité Hospital, Berlin. For profuse menstruation at the menopause the older treatment comprised ergot and irrigations, with curettage as a reserve resource and hysterectomy as a last resort. To-day the treatment consists mainly in destroying the ovaries functionally with radiography. It must be confessed, however, that this resource is by no means always free from danger. A correct diagnosis must, of course, be made, for to proceed too hastily to radiography might cause the operator to overlook a beginning cancer or a small submucous myoma—in the latter case the error would only be technical as the rays could be the treatment of choice under such circumstances, although many would doubtless prefer extirpation. If a high degree of acute anemia is associated with the hemorrhage hysterectomy might be the indication of necessity. The older the patient the more prompt should be the cure. Naturally everything depends upon selection of material and aptness of technique, both as regards outlook or recovery, and the prevention of accidents due to the treatment.

A New Method for Examination of Lumbar Punctates.—Braun and Husler isolate five groups of punctates. The first is characteristic of tuberculous meningitis or perhaps of meningitis in general, although the authors' test may be made especially valuable for the latter. The test is simple, consisting in the addition of a very dilute hydrochloric acid to a certain quantity of punctate. The acid, tenth-normal, is diluted with 299 parts of distilled water, and one c.c. of punctate is added to 5 c.c. of dilute acid. In meningitis the mixture becomes turbid perhaps in a few moments or perhaps not until a half hour. This reaction never occurs in a normal punctate. The second group of punctates is that of acute purulent meningitis, but the reaction while positive in these cases is for obvious reasons of no special diagnostic value. Other groups of punctates are respectively those of paralysis, cases of any sort which simulate meningitis, and miscellaneous unclassified cases. The only actual claims made are two. Tuberculous meningitis may be diagnosticated outright, since it would not be confused clinically with acute purulent meningitis, while meningitis of any sort may be excluded by negative reaction.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

Cough and Hoarseness.—An occasional cough will usually be too trivial to report if a careful search has failed to reveal a serious cause. It may arise from a slight congestion of the fauces or pharnyx, a few granulations at the back of the throat, or a long uvula, or it may be due purely to nervousness, all these conditions being inconsequential. When the cough is habitual or constant, however, the examiner should report it in any event as well as making a rigid examination.

Respirations.—Deviations from a normal rate of respiration are seldom met with in life insurance examining. Nevertheless the rate should always be taken, and if it varies much from 18 to 20 a minute the cause should be looked for. Labored respiration is encountered occasionally in applicants who are subject to chronic bronchitis, emphysema or asthma. Chronic hoarseness or huskiness should always be reported with the cause.

Expansion of the Chest.—Examiners often refer to a large chest capacity as a valuable indication of the manner in which the lungs perform their functions. In an ordinary healthy man of average height and build the difference between inspiration and expiration is about two to three inches, whereas in abnormal conditions there may not be an inch in difference.

Great expansion of the chest is often the result of practice. On the other hand, deficient expansion may be encountered in individuals who, though robust and healthy, are stout or sedentary in their habits, and, through lack of practice, do not know how to expand their chest, especially when they are asked to do so. The examiner will have to give some instruction to such applicants before he can get them to show their normal capacity.

In incipient or even in the more advanced but still early ages of pulmonary disease the movements of the chest may be so unrestricted that the expansion will afford no evidence of trouble.

The Lungs.—Every examination of the lungs should be made with the chest bared in accordance with the suggestions and illustrations previously given in the section under "General Methods in Examination." If those precautions are observed the examiner will be in a position to discover any lesion from the apex to the base.

It must always be kept in mind by the examiner that he is apt to meet cases of pulmonary tuberculosis in the very earliest stages when the signs are easily overlooked. Most of these applicants will not have any history of previous cough, hemoptysis, loss of weight, night sweats, or a bad family history to put him on his guard, so that in these cases more than any other, probably, grave errors are avoided only by the exercise of the utmost care and thoroughness in every examination. Unless the examination is made in a quiet place where there are no distractions and the chest is properly bared, the signs of incipient disease in the chest will often escape detection. While these remarks apply to all applicants, they are particularly fitting to light weights with poor family histories and personal histories of dyspepsia or indigestion.

Examiners should remember that every deviation in the chest from the rule does not necessarily indicate a diseased condition. The physiological differences in the percussion note or in the respiratory sounds between the two sides of the chest may be considerably exaggerated in healthy individuals and, with a few, similar conditions, should not be recorded after an extendeed examination has eliminated all possible diseased conditions. A slight prolongation of the expiratory sound, if uniform on both sides and not caused by emphysema, a few crackles bilateral at the base and no dullness showing the presence of some old adhesions without thickening of the pleura, or the slightly harsh respiratory murmur in elderly as compared to that in younger people are a few of the conditions not worthy of reporting, always provided that extra care has been taken to discover more serious causes.

Applicants who have had pleurisy are acceptable after a reasonable length of time has elapsed, provided there was no suspicion of tuberculosis and that no thickening of the pleura remains; in these cases a few friction sounds may be expected. A full history as to the date, duration, complications, if any, whether it was dry, with effusion or purulent, and whether there was any suspicion of tuberculosis will be required, and the only one who can intelligently supply these data is the attending physician. The applicant is expected to furnish this statement from his physician. In addition to this the examiner must give a definite, explicit description of the physical signs remaining.

Acute Colds.—Applicants frequently present themselves for examination while subject to acute colds. The ailment may seem too trivial to report. It must not be forgotten, however, that an ordinary cold is often the precursor to pneumonia or bronchitis, especially if the applicant is indiscreet while under the influence of the cold. It is the duty of the examiner, therefore, to mention ordinary colds in the report and make a re-examination later, informing the home office when full and complete recovery has taken place.

Pulmonary Emphysema.—Keller tells of examining in 1878 a country messenger 33 years old, and advising special rates because of moderate emphysema and the fact that the applicant had to do a good deal of hill climbing in his occupation. The insurance company refused the application altogether. The applicant continued at his work, and in the year 1912 Keller was called to treat him for trouble in walking, weakness, etc. Keller found a high degree of arteriosclerosis, which may have been due to the constant and excessive use of alcohol; singularly enough the patient, now 67 years old, showed almost the same degree of emphysema as on the first examination for insurance. This case has taught Keller not to be too fearful of recommending applicants with emphysema for life insurance; while numerous minor symptoms and complaints may be due to this affection, severe grades of it threatening life or shortening life expectation are rarely met with. An additional premium may be justifiable in cases of emphysema, but refusing insurance is bad business as well as unfair to the applicant.—*Blätter für Vertrauensärzte der Lebensversicherung,* March and April, 1912.

American Association of Medical Examiners.—The next annual meeting of this association will be held at Minneapolis, June 2 and 3, 1912, under the presidency of Dr. Frank W. Foxworthy of Indianapolis. The secretary is Dr. G. Strohbach, Miami Building, Cincinnati.

Book Reviews.

Urology. The Diseases of the Urinary Tract in Men and Women. A Book for Practitioners and Students. By Ramon Guiteras, M.D. (Harv.), Professor of Genito-urinary Surgery, New York Post-Graduate Medical School; Visiting Surgeon to the Columbus and Post-Graduate Hospitals; Consulting Surgeon to the City and French Hospitals; Formerly Professor of Anatomy, Operative Surgery and Gynecology, Post-Graduate Medical School, and Visiting Surgeon to the Department of Genitourinary Diseases and Gynecology, New York City Hospital; Member of the American Medical Association, the American Urological Association, the French Urological Association, the American Public Health Association, the American Association of Genitourinary Surgeons, the American Association of Obstetricians and Gynecologists, the Association of Military Surgeons of the United States, the American Society of Tropical Medicine, the New York Academy of Medicine, and the Harvard Medical Society. With Nine Hundred and Forty-three Illustrations in Text and Seven Plates. Volumes I and II. Price $10.00. New York and London: D. Appleton & Company, 1912.

The two volumes before us comprise a complete treatise on the diseases of the urinary tract in both sexes by a man whose long activity as a practical surgeon in this field and as a teacher to post-graduate students have made him peculiarly fitted to be the author of such a book. Because of such experience Dr. Guiteras has succeeded in presenting his subject in such a manner as to leave nothing to be desired in clearness of exposition and directness of instructions. The wealth of illustrations, almost a thousand, add greatly to the teaching value of his work.

Perhaps the best way of acquainting the reader with the scope of the work is to quote some of the chapter headings which follow: History and Diseases of the Urinary Tract, the Anatomy of the Genitourinary Tract, the Urine, Discharges, the Blood in Relation to Urology, Urological Equipment, Sterilization of Instruments and Apparatus, Technique of Instrumentation, Urethroscopy, Cystoscopy, Special Urinary Symptoms, Urinary Fever, Urinary Infection, the History of the Case, General Symptoms, Examination of Patients, Urological Therapeutics, Anesthesia in Urology, Diseases of Metabolism, Methods of Examining the Kidney, Kidney Injuries, Movable Kidney, Nonsuppurative Neophritis, Nephrolithiasis, etc., etc. The second volume is devoted mainly to the diseases of the bladder, of the prostate, of the urethra, of the testicles and scrotum, and the various chapters are just as detailed in contents as those mentioned above.

The book must become a necessary equipment to every specialist in genitourinary disease. On the other hand, no better treatise can be recommended to a non-specialist who desires to possess one authoritative work on the subject for purposes of reference.

Spondylotherapy. Physiotherapy of the Spine Based on a Study of Clinical Physiology. By Albert Abrams, A.M., M.D., F.R.M.S., Consulting Physician to the Mount Zion and French Hospitals, San Francisco; Formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College (Department of Medicine, Leland Stanford Junior University), San Francisco. Third Edition, Enlarged. San Francisco: Philopolis Press, 1912.

The fact has been known for long empirically that applications to and manipulations of the spine produced certain favorable effects upon some conditions which other treatment had failed to benefit. Thus it has come to pass that spinal massage and so on in the hands of practitioners of some schools have been lauded as cure alls, and this form of treatment has gained the confidence of a large section of the community. Dr. Abrams has thoroughly investigated various visceral reflexes which bear his name and has thereby been led into a deeper study of spinal therapeutics, the results of which he has embodied in a work on the subject. The book has gone through two editions, which speaks well for its reception, while the present edition has been enlarged by the addition of seven chapters and fifty new illustrations. In the preface to the third edition and in a chapter of the book, the author takes the opportunity of criticising some of the reviewers of the former editions and expresses regret that our medical journals have not yet attained the Utopian condition when they are eager to give space to the protestations of an author who feels that his work has been misinterpreted or unjustly criticized. It should be both to the advantage of readers, the journal and the author that the *raison d'être* of a work should be made clear, and therefore medical journals should not be averse to publishing explanatory letters. However, Dr. Abrams explains with commendable lucidity in the book itself spondylotherapy from seemingly every possible standpoint. The work is interesting and instructive even if one is unable to wholly believe that the method of treatment is indicated in all the complaints to which the author refers. The book is well printed and the illustrations are clear. The additions double the size of the work and provide suggestive reading.

Die Diagnostische und Prognostiche Bedeutung der Harnsedimente nach Neueren Anschauungen. Von Dr. C. Posner, Prof. au der Universität Berlin. Price 1.40 marks. Halle: Carl Marhold Verlagsbuchhandlung, 1912.

In this excellent contribution to the series of monographs on metabolic disorders edited by Dr. Albu, the author discusses the significance of urinary sediments. In spite of the extensive consideration he gives to the matter of the inorganic substances that present themselves in this connection it is evident that there is still very little reason for attaching much importance to their appearance. In most instances the occurrence of deposits of urates, phosphates, uric acid, oxalates, etc., is dependent on physical rather than metabolic causes, and the few conditions under which this is not the case are satisfactorily described. The question as to whether or not casts can appear without the presence of albumin in the urine is still regarded by many authorities as an open one, but Posner is strongly of the opinion that they may, rarely, be found in albumin free urine. He also emphasizes the fact that it is impossible to determine the point of origin along the genitourinary tract of the epithelial cells found in the sediment—a fact which some microscopists still find it difficult to accept. The utility of the dark field method of illumination, and of the polarizing microscope in studying the organized sediments is pointed out, and there is also a brief discussion of the microorganisms to be found.

Investigations on Dysentery in Fiji, During the Year 1910. By P. H. Bahr, M.A., M.B., B.C., D.T.M.&H., Cantab., M.R.C.S., Eng., L.R.C.P., Lond. Together with an Account of the Occurrence and Spread of Dysentery in the Pacific in Former Years by B. Gianvill Cormey, I.S.O., M.R.C.S., for Twenty Years Chief Medical Officer, Fiji. With Colored and Monochrome Plates and Many Charts. Price 6 shillings net. London: Witherby & Co., 1912.

Dr. Bahr studied dysentery for thirteen months in Fiji, and this report to the London School of Tropical Medicine embodies the results of his investigations. The report is preceded by a remarkably interesting paper by Dr. G. Corney, who was for twenty years chief medical officer of the colony. The mortality from dysentery has greatly lessened since Dr. Corney first went to Fiji and has continued to decrease in virulence. Dr. Bahr investigated the disease bacteriologically, clinically, and from the standpoints of pathology, epidemiology, treatment, and prophylaxis. The chapter dealing with amebic dysentery is especially instructive and other points of particular interest are portions of the book concerned with the treatment of acute dysentery by intestinal disinfectants and the antiserum treatment. Bahr is unable to draw any definite conclusions from the treatment, but is inclined to think that the combined method of antiserum injection, together with the administration of salines and disinfectants, gives the best results. The report, which is issued in the form of a supplement of the *Journal of the London School of Tropical Medicine*, is well printed and contains some excellent colored and monochrome plates. It is a useful addition to our constantly increasing store of knowledge concerning tropical diseases.

Ueber Pyodermien, die Infektionen der Haut mit den banalen Eiterregern. Von J. Jadassohn, Bern, Sammlung Jadassohn, Band I, Heft. 2. Price M. 1.80. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1912.

In this monograph the author proposes a new nomenclature and classification for certain skin diseases. This is based upon the etiological factor and therefore upon firm scientific grounds, a method of attack which dermatology as a whole sadly lacks. Those skin diseases which are due to the staphylococcus and the streptococcus are clearly described and classified. In some instances the epidemiology of the affection is discussed. Therapeutics and prognosis are briefly referred to at the end of the work.

A Manual of Surgical Treatment by Sir W. Watson Cheyne, Bart., C.B.D.Sc., LL.D., F.R.C.S., F.R.S., Hon. Surgeon in Ordinary to H. M. the King; Senior Surgeon to King's College Hospital, and F. F. Burghard, M.S. (Lond.), F.R.C.S. Surgeon to King's College Hospital and Senior Surgeon to the Children's Hospital, Paddington Green. New Edition, entirely revised and largely rewritten with the assistance of T. P. Legg, M.S. (Lond.), F.R.C.S. Surgeon to the Royal Free Hospital; Assistant Surgeon to King's College Hospital, and Arthur Edmonds, M.S. (Lond.), F.R.C.S. Surgeon to the Great Northern Central Hospital; Surgeon to Out-Patients, The Children's Hospital, Paddington Green. In Five Volumes, Vol. I. Price $6.00. Philadelphia and New York: Lea & Febiger, 1912.

The first edition of this work appeared about a dozen years ago and was at once welcomed by surgeons. It is now presented in a revised form, with ample additions and such changes as are necessary to bring it up to date. The work appeals to the practitioner rather than to the student. The latter is concerned more especially with the pathology, symptomatology and diagnosis of surgical conditions; whereas the practitioner frequently requires full and detailed information as to the best methods of treatment. The authors have made a careful selection of methods, and only present here what they have found by personal experience to be of value. The present volume includes sections on inflammation, suppuration, ulceration, gangrene, wounds, and their complications; burns, scalds, and frostbites; infective diseases of wounds; affections of cicatrices; syphilis; tuberculosis; tumors, deformities of the fingers and toes; flat-foot; club-foot; curved tibia and fibula; genu vaigum, varum, and recurvatum; curvatures of the neck of the femur; congenital dislocation of the hip; kyphosis, and scoliosis. There is an appendix with two very complete chapters on anesthetics and blood examination in surgical conditions. The book is not at all narrow in its scope; and the title "Surgical Treatment" is very liberally interpreted. In the chapter on syphilis will be found a discussion on Salvarsan, and a description of its administration by the intravenous method; and under the heading of scoliosis is a full account, with illustrations, of exercises which have been found useful in this condition. The reader may not agree with every statement contained in the volume, for example in the discussion on asepsis and antisepsis on pages 99 and 153; but the authors describe both methods, and then give their preference, with reasons for the same. For the beginner, or one with but little experience, the present work is invaluable; at the same time most surgeons will find it a useful addition to their library.

Cornell University Medical Bulletin. Studies from the Department of Medicine, including Therapeutics and Applied Pharmacology. New York: Cornell University, 1912.

This volume contains a number of reprints of articles by several members of the Cornell University Medical College. Among the contributors are Doctors W. G. Thompson, L. A. Conner, W. L. Niles, F. S. Meara, T. W. Hastings, B. R. Hoobler, M. Neustadter, W. C. Thro, H. J. Schwartz W. H. Sheldon, A. I. Ringer, A. C. Crehore, W. Coleman, and E. F. DuBois. As all of these papers have appeared in various medical journals it is more than likely that our readers have already seen them, either in their original form or in abstract.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia, March 1, 1912. Price $6.00 per annum. Philadelphia and New York: Lea and Febiger, 1912.

The first article in the current number of Progressive Medicine is by C. H. Frazier, on Surgery of the Head, Neck, and Thorax. It begins with a useful and timely summary of what is known about the Hypophysis. The whole of this article, of nearly one hundred pages, is most valuable. The subject of Infectious diseases, including Acute Rheumatism, Croupous Pneumonia, and Influenza, is by J. Ruhrah. Curiously, neither Pneumonia, Rheumatism, nor Influenza occurs in the index. F. Crandall contributes the article on Diseases of Children, and D. B. Kyle and A. Duel supply the articles on Rhinology and Laryngology, and Otology, respectively. Colon bacillus infection, in the index, should contain a reference to page 256.

A Compend of Human Physiology. Especially Adapted for the Use of Medical Students. By Albert P. Brubaker, A.M., M.D., Author of "A Text-Book of Physiology"; Professor of Physiology and Medical Jurisprudence in the Jefferson Medical College; formerly Professor of Physiology in the Pennsylvania College of Dental Surgery; Lecturer on Anatomy and Physiology in the Drexel Institute of Art, Science and Industry; Fellow of the College of Physicians of Philadelphia. Thirteenth edition, with 26 illustrations. Price $1.25 net. Philadelphia: P. Blakiston's Son & Co., 1912.

This compend on physiology has long been a favorite with medical students, and doubtless the new edition will enjoy the popularity of its predecessors. We note the omission of the "Table of Physiologic Constants," which was a useful feature of the former editions. In the index we find no mention of Spleen, Metabolism, Ductless Glands, Feces, Reaction of Degeneration, Respiratory Quotient, and many other terms which a student might expect to find there.

Elements of Hydrotherapy for Nurses. By George Knapp Abbott, M.D., Dean of the Faculty and Professor of Hydrotherapy and Practice of Medicine in the College of Medical Evangelists, Loma Linda, Cal. Washington, D. C.: Review and Herald Publishing Association.

If, as the author asserts in the preface of this book, there is an "urgent need of a nurses' text-book on hydrotherapy," he is certainly one of the first to come forward and aid in filling this deplorable gap in the already voluminous literature supplied to the nursing profession. The first part of the book deals with the physiological effects of water; the second with the therapeutics, and the third with the technique of hydrotherapy. The author is an ardent advocate of this method of therapy, and prefers it to quinine in the treatment of malaria. The book should prove of service to nurses who have to look after patients undergoing this form of treatment.

Diseases of the Genitourinary Organs and the Kidney. By Robert H. Greene, A.M., M.D., Professor of Genitourinary Surgery, Medical Department of Fordham University; Genitourinary Surgeon to the City and to the French Hospitals, New York City; and Harlow Brooks, M.D., Assistant Professor of Clinical Medicine, University and Bellevue Hospital Medical School; Visiting Physician to the City Hospital and to the Montefiore Home for Chronic Invalids, New York City; Consulting Pathologist to the Muhlenberg Hospital, Plainfield, and to the Hackensack Hospital, N. J. Third Edition, Revised and Enlarged, with 339 Illustrations. Price $5.00. Philadelphia and London: W. B. Saunders Company, 1912.

It is quite fitting that a work of this kind should be written through the collaboration of a physician and a surgeon, for in no domain of medicine more than in diseases of the genitourinary organs and the kidney do medicine and surgery meet in such a wide territory of common jurisdiction. The present edition not only attests the popularity which this work has achieved, but also signalizes the distinct advances that have been made within recent years in the study of genitourinary diseases. Thus the newer tests showing permeability of the kidney, including the phenolsulphonephthalein test are fully described. It is difficult to pick out any one feature of this work for special commendation, so admirably have all the various phases of the medical and surgical treatment of the diseases of the kidneys and genitourinary organs been described. The work is an eminently practical one; the subject of treatment being presented in satisfying detail. As in the former editions the illustrations, typography, and binding leave nothing to be desired.

A Pocket Formulary. By E. Quin Thornton, M.D., Assistant Professor of Materia Medica in the Jefferson Medical College, Philadelphia. Tenth Edition, Revised. Price $1.50. Philadelphia and New York: Lea & Febiger, 1912.

The appearance of the tenth edition of this work amply testifies to its popularity. That it has kept pace with the recent advances in medical science is indicated by the recognition given in the present edition to salvarsan, human blood serum, antimeningitis serum, and bacterial vaccines. The various diseases are arranged in alphabetical order, and under each are given a large variety of prescriptions. A useful feature of this work is the fact that in connection with each prescription there is noted the definite indication which it is designed to meet. The book is compact, well printed, and handsomely bound.

Society Reports.

CONNECTICUT STATE MEDICAL SOCIETY.

One Hundred and Twentieth Annual Meeting, Held at New Haven, May 22 and 23, 1912.

(*Concluded from page 44.*)

Adventitious Bands about the Cecum.—Dr. Joseph M. Flint, of New Haven, said that the membranous pericolitis, occurring about the cecum had a more or less regular distribution, and might be divided into three groups. That the first group extended from the parietal peritoneum, near the hepatic flexure, and on to the lateral and ventral aspect of the ascending colon, leaving the caput ceci free. Occasionally those might cover the cecum and the appendix as well. That the second group included more limited veils, which extended from a corresponding part of the peritoneum over the caput ceci, and involved the appendix. In those cases the ascending colon was free. The third group included veils with a similar origin, which might pass over the colon and become continuous with the omentum along the mesial aspect of the large bowel. He also said that the first two types of veils resulted from an extension of the usual fusion that occurred between the rotated intestine and the parietal peritoneum; and that the fine delicate attachments sometimes extended over onto the ventral aspect of the ascending colon, and were drawn out into membranes in the subsequent descent. Those membranes, or veils, usually caused no symptoms; but, when badly placed, they produced obstruction, and involved or kinked the appendix. He explained that Lane's band was due to an extension of the process of fusion to the terminal portion of the ileum, and that it was found in embryos. Descent, when that attachment was present, had often shortened the posterior leaf of the mesentery and kinked the gut; and an embryonic band had occasionally given symptoms between the gallbladder and transverse colon and omentum.

Dr. William F. Verdi of New Haven remarked that it had been ten or twelve years since he first observed the pericolic bands, and that he had found four types, instead of three. He had been unable to decide definitely whether it represented embryological structures, while the bands did resemble normal structures, yet they were of so long standing that they appeared to be congenital. Besides, they did not cause so much trouble as one might think. He stated that a few years before he had operated on a patient who had had a *bonâ fide* intestinal obstruction, which was due to a Lane's kink; but that he had also operated on others in whom the obstruction had produced no symptoms, the condition having been found in the course of his operations for other causes.

Dr. Everett J. McKnight of Hartford said that for some time he had felt that many of the bands which had been met with at the time of operation were congenital. He cited a case that he had operated on seven or eight years before, in which the patient—a woman—had presented symptoms of gradually increasing obstruction, which he had thought to be due to malignant disease of the cecum. When incision was made into the right rectus no tumor was found; but there was a marked membrane attached over the cecum and ascending colon. Finally he found a small, annular carcinoma of the sigmoid, which he operated on. Dr. Everett thought it was difficult to decide what should be done when those adhesions were met with, and seemed to feel that every man would have to decide for himself whether they were causing trouble or not; if they were, section should be made.

Dr. Flint declared that it had come to be the custom to associate either a Lane's band or appendicitis with those symptoms.

The Surgical Treatment of Goiter.—Dr. O. C. Smith of Hartford said that the term goiter was very broad and far from distinctive, and that it indicated a morbid enlargement of the thyroid gland. The cause, though unknown, had many variable anatomical features. In the case of colloid, cystic, and nodular goiter, the risk of operation was small, and the relief generally permanent; while with the swollen thyroid, of puberty and pregnancy, the case called for rest, hygiene, and conservation of the nervous system. Dr. Smith felt that with the improvement in technique and methods, and if discrimination were used in the selection of cases, the hazard of operation for simple goiter was negligible; while in hyperthyroidism, the result ought to be as satisfactory, and the mortality lower than in most other acute lesions, all of which demanded surgery that had as its goal the saving of life and the minimizing of morbidity.

Dr. Henry M. Lee of New London remarked that in approaching that subject one should always have in mind the varying and conflicting syndromes that would be presented—from the picture of a large cystic goiter, without symptoms, to the hyperthyroid cases which seemed as though they would run to destruction. He said that the best classification that had been made was the one by Dr. Bacon; and that in approaching such cases one should subject them first to a critical diagnosis, to determine what type they belonged to, and should then treat them medically before intervening surgically.

Dr. Leonard W. Bacon, Jr., of New Haven, said that acute strumitis was not a common difficulty, but that he had seen a case with distinct local symptoms of inflammation and the classical signs of inflammation in the thyroid region, but with no general symptoms of disturbance in the thyroid function. He did not consider the type of goiter that extended beneath the sternum, and possibly had its most considerable development there, as presenting very grave difficulty. The fact that it rose and fell with respiration indicated that its attachments were very loose. He had sometimes removed from behind the sternum one that promised to be a mass the size of the fist. In regard to the point made by Dr. Smith as to the discrepancy between the clinical and the etiological findings, Dr. Bacon said that he had found, in one case that he had operated on, flakes of true bone disseminated throughout the gland. In the case of enlarged and soft goiter, he said that a simple way in which to make the diagnosis was to thrust the whole goiter to each side, alternately, and then palpate the other side. In this way one could get evidence of enlargement that one could not get when the goiter was in the median line of the neck. He thought that the author of the paper did not do entire justice to the benefits that might be received from medicinal or quasi-medicinal treatment.

Dr. Daniel F. Sullivan of Hartford said that it was his belief, also, that the diagnosis of exophthalmic goiter was not an easy matter, and that the treatment did not entirely belong to the surgeon. Rest and proper environment would often do more for a case than surgery; but where a patient demanded an operation, or could not submit to a long course of treatment, then the operation should be done—though it was always dangerous, and often unhappy for the good reputation of the surgeon.

Dr. Rush said that the condition found histologically after the operation was not always that which might have been found had the gland been removed earlier.

Dr. William W. Brackett of New Britain, said that all the symptoms found to exist where there was a goiter, were not always the result of the thyroid trouble; one should get behind the thyroid and see what was producing the trouble. He remarked that in all schools there was a certain percentage of the children who had enlarged thyroids, and that the parents should be told that the thyroids of their child were not strong and that he must be kept away from too much excitement.

Dr. Smith said that hyperthyroidism was a medical disease and should be treated medically; but should medical treatment fail, then surgical treatment was essential. He reiterated that rest, hygiene, and the use of sera were important in the treatment of that disease.

The Medical School.—Dr. John G. Stanton of New London delivered this as the President's address. He did not consider the medical schools of today fully up to the requirements necessary to a thorough foundation and superstructure for instruction, though he remarked that there were a few schools where the student had to fulfill the requirements of a full, thorough, and well-grounded medical education before he could gain his diploma. He felt that the fault did not lie entirely with the too numerous low-grade medical schools, but with the public, who were to blame fully as much as the proprietors of the medical "gristmills." The question of medical education confronted a condition, not a theory. He declared that the task before those who were competent to mold public opinion was to educate the citizens, and satisfy them that the medical profession were actuated by an honest desire in demanding a higher standard of medical education. And that the ultimate results sought meant a conservation of the public's best interests, in producing a class of physicians who should be thoroughly educated in medicine and competent to assume the responsibilities of a profession that entered so deeply into the family relation.

Recent Developments in the Diagnosis and Treatment of Tuberculosis.—Dr. William B. Bartlett of Hartford mentioned, as the most important developments in the realm of tuberculosis in the past few years, the

following: (1) Increased accommodations for the tuberculosis invalids and the growth of the sanatorium idea; (2) the evidence that bovine tubercle bacilli caused many forms of surgical tuberculosis in children, that it was much less frequent in adults, and that it might even cause pulmonary infection; (3) the development of the *x*-ray in diagnosis, and the relegation of the tuberculin test to a place of secondary diagnostic importance; (4) the development of lung surgery; (5) the evidence that the average patient will do far better when fed moderately and sanely than when stuffed until his stomach rebels.

Dr. Frank B. Standish of New Haven said that great advance had been made with regard to the *x*-ray work. One of the most interesting things in the way of treatment was the method of compressing the lung by means of an artificial pneumothorax. This operation had been used mostly in early cases. He felt that the danger of contagion had been treated too lightly; that enough care had not been used to prevent contagion in the tenement-house districts.

Dr. Leonard J. Loewe of Falls Village said that he was impressed with the uncertainty manifested in most of the tuberculosis tests and the lack of something definite in the different diagnostic signs. He felt that the only certain method was a physical examination, made by a competent man. He said that tuberculosis was generally latent in the patient's body for some time before it was manifested after an illness or nervous breakdown; that there was no specific as yet, and that he believed the greatest advance in the future would be along the line of tuberculin. He was heartily in favor of the sanatorium treatment, with complete rest at first, and a little work later on, as the patient grew stronger.

Dr. Stephen J. Maher of New Haven felt that in pulmonary tuberculosis, tuberculin was secondarily important to proper physical and microscopic examination; but in other forms tuberculin was of primary diagnostic importance.

Dr. David Russell Lyman said that more would have to be done in regard to the eradication of bovine tuberculosis before human tuberculosis could be stamped out. He declared that tubercle bacilli were served up at the tables throughout the land, and in the nurseries, every day, and that no great strides could be made in the State until it was made impossible for dealers to import tuberculous milk cows into Connecticut.

Dr. Bartlett reiterated the idea that the tuberculin test had been given a place of secondary importance, not on account of its therapeutic value, but on account of its diagnostic value.

The Diagnosis and Complications of Atypical Pneumonia.—Dr. Kate C. Mead of Middletown said that during the winter months pneumonia led all other diseases as a cause of death in Connecticut. She observed that a typical pneumonia was difficult to diagnose, and that its presence had often to be surmised, as no positive signs were apparent, especially in children and old persons. Where nephritis was one of the complications of pneumonia, it was apt to prove fatal. Pregnancy was a rarer complication. She said pneumonia was sometimes mistaken for appendicitis in young children, and that there was a similarity in the pain and its location during the first few days of the disease. Dr. Mead thought that the diagnosis would be greatly aided by studying the relation between the temperature, pulse, respiration, and the blood pressure, and by finding the pneumococcus in the blood.

Dr. Fritz C. Hyde of Greenwich considered it a deplorable fact that many physicians made a diagnosis of pneumonia in cases in which no signs of that disease could be found. He felt that the leucocyte count often gave a valuable hint; but differed with Dr. Mead in the idea that no case had ever recovered where there was an irregular heart-action before the crisis.

Dr. Chas. J. Foote of New Haven thought that the title of Dr. Mead's paper was somewhat misleading, because it dealt with pneumococcic infection, which was quite different from pneumonia. Pulmonary pneumonia was simply one manifestation of pneumococcus infection, he said, and atypical pneumonia was caused by some other organism. If there was a double infection, there would be an atypical run of pneumonia; but if there was simply infection with the pneumococcus the course would be fairly typical.

Dr. George Blumer of New Haven said that he had seen four different kinds of what he called atypical pneumonia, or pneumonia which simulated other diseases. There was the form simulating meningitis; that which simulated appendicitis; the third type, which was characterized by immense board-like, abdominal distention; while the fourth occurring in young infants, was associated with earache, and was usually diagnosed as otitis media.

The State Board of Health.—Dr. Edward K. Root of Hartford said that the State Board of Health was created to carry out two functions. The first was to supervise the vital statistics of the State; but the second was too broad to go into detail with, though one of the duties which the second function involved was inspection of public hospitals, schools, etc. The author stated that the board had practically no mandatory powers over any citizen, over his person or his property unless he was suffering from cholera or yellow fever, which was epidemic. The only authority the State had over the different towns was that of appproval; that it could not quarantine. Dr. Root declared that the State Board of Health should have power to issue rules in matters concerning the preservation of public health, which rules should be mandatory on all towns alike. The board should also have the general oversight and authority of public water supplies, public systems of sewage, the pollution of streams, rivers, and harbors throughout the State. That all matters involving the construction of large public works, the collection and distribution of public water supplies, could only effectively be made by the State, and the board was the logical and proper authority to have charge of those matters. He said that if the members of that Society would cooperate and urge upon the legislators the desirability and necessity of concerted action on the questions before mentioned, they would soon gain legislative sanction.

Dr. Chas. P. Botsford of Hartford remarked that most of those present knew what very large powers other State Boards of Health had, and that he, personally, thought that the time had passed when the towns of Connecticut could settle their sanitary affairs for themselves, without regard to their neighbors, and that if the State was to keep up with the progress of sanitary advancement, more power must be given the Connecticut State Board of Health.

Dr. H. D. Pease of New York City said that New York State had passed through the same stages that Connecticut was now going through. Many efforts were made, some of which were successful, while he was a member of the board, to obtain powers outlined by Dr. Root in his paper, as desirable. He said there was no power given the Federal Government by the Constitution that permitted it, directly or indirectly, to step in and have anything to do with health matters in the several States; but that the powers so carefully outlined by Dr. Root should be given the State Board.

Dr. William H. Donaldson of Fairfield declared that it was a disgrace to the medical profession that they should go on under the present administration of sanitary matters. The medical profession of Connecticut had, for years, been under the thumb of the legal profession, and anything they sought for advancement or improvement could only be had by the consent of the legal profession. He said that it was time for their profession to take a decided stand and do something; they should all use their influence to insure the passage of the Owen Bill, for once it was carried through they would have the national power, which could direct them in the constitution of their State Board.

Officers.—The following officers were elected: *President*, Dr. E. T. Bradstreet of Meriden; *Vice-Presidents*, Drs. Frederick Gilnack of Rockville, and A. E. Barber of Bethel; *Secretary*, Dr. Walder Tileston of New Haven; *Treasurer*, Dr. Joseph H. Townsend of New Haven.

The next meeting will be at Hartford the latter part of May, 1913.

AMERICAN PEDIATRIC SOCIETY.

Annual Meeting, Held at Hot Springs, Va., May 29, 30, and 31, 1912.

The President, Dr. Walter Lester Carr of New York, in the Chair.

President's Address: The Relation of the American Pediatric Society to the Movements for the Reduction of Mortality in Infancy and Childhood.—Dr. Walter Lester Carr made this address, in which he referred to the work of conservation to which public sentiment had been awakened in all lines, but more especially to the awakened appreciation of the value of health and life. It was only necessary to look over the Index of the Transactions of this Society to note the changed point of view of the profession as evidenced by the titles of papers presented in recent years. Now the topics con-

cerned nutrition and problems of metabolism, while formerly the subjects were more often of clinical and pathological interest. This society and other medical societies had felt the influence of organizations outside of their direct sphere of activity. Some of these influences had made a change in their attitude toward disease. Popular knowledge of science and medicine had led to the formation of societies for the public good along educational lines. One such society, the aim of which had been not only medical, but also progressive and educational, had brought to discussion the views of clinicians and sanitarians and by the publicity given its meetings and publications had aroused public sentiment and effected many reforms. Boards of Health and Milk Commissions had enlarged the sphere of preventive medicine and their efforts had been reflected in this society more largely perhaps than in any similar body of medical men. Infant mortality, child labor, and physical betterment, although interwoven with economic problems, confronted them and became more important with a lowered birth rate, and it was an essential requirement that the surviving members of the race should be endowed with the highest potential efficiency to improve their physical standards and to build upon them a more controlled and stable human machine. Allowing that there were many aspects of these problems that could not be made part of the regular program of these meetings, they had a responsibility which their organization could not pass on to those whose knowledge was less definite than theirs, nor could they in justice to themselves and the community relegate the topics to other societies without giving them expert advice. They could widen their sphere of usefulness by having representatives appointed to affiliate with organizations having to do with child betterment. Such representatives could confer on problems of social, economic, and pedagogic importance and would be ready to present information of the physical needs of the growing child and the dangers of pathological influences. After referring to the work being done all over the civilized world for the reduction of infant mortality, and citing statistics showing the decrease of infant mortality from all causes, Dr. Carr said that he thought their society had been instrumental in bringing about some of the results. He thought that by constant repetition they had impressed physicians and the laity with the fact that prevention of disease was possible, and a study of cause was better than treatment of effect. Three things were essential to this society in order to secure its vitality and usefulness. First, they must add to their study of diseases observed in infancy and childhood from the standpoint of their pathological and clinical histories, comparative and tabulated records and methods of precision, so that they might judge more accurately of the semiology of disease. Second, they should have a program relating to metabolic processes, more especially to those of infancy and childhood, arranged so that investigators would present to this society for discussion the results of laboratory investigations that bore on their clinical studies. From the nature of investigations made necessary along lines of development and physiological growth the laboratory offered the best field for experimental work and the pure clinician should await the deductions of members of the society who were laboratory workers. Third, the society should endorse movements having to do with physiological and economic problems relating to infancy and childhood, particularly those of mortality and disease. The society could not stand as the highest pediatric body in this country if it failed to recognize the many influences that were at work to lower the mortality in infancy and childhood, nor could its opinions be authoritative unless it co-operated officially with other agencies having this object in view. They should be ready to give hearty aid and approval to societies that approached pediatrics from standpoints other than medical.

Coagulation of the Blood in Infants and Children.—Dr. Howard Childs Carpenter and Dr. Clayton Gittings of Philadelphia presented this communication. They stated that the large majority of observations had been made upon adults and that it seemed desirable to extend the study to infants and children, both in health and disease, in order to decide, if possible, upon a standard for comparison. They considered the various coagulometers in use and the results obtained by other observers. Their clinical material had been drawn from the Children's Department of the Philadelphia General, University and Presbyterian Hospitals, and the Children's Hospital. They had made 192 examinations on 176 patients. Of these, 18 examinations of 16 patients had an undetermined coagulation time and re-examinations could not be made. Of 160 patients which gave a positive coagulation time 35 were healthy, without ascertainable disease, except such afflictions as ring-worm of the scalp and scabies (8 cases); 125 cases suffered from a variety of diseases. Grouping all the healthy cases and those suffering from disease they had found that in healthy cases the average coagulation time in 39 examinations was 9.4 minutes, the times having varied from five to fourteen minutes. In the cases that were not healthy the average coagulation time in 135 examinations had been 9.7 minutes, and had varied from five to sixteen minutes. This showed an unimportant difference between the well and the sick. The usual statement found in the literature was to the effect that there was very little difference between the coagulation time in childhood as compared with adult life, except that during the first few days of life a delay was observed. Their results for older infants and children showed no material differences from the accepted result, although the average for childhood was higher than the average for adults tested by the Biffi method. The author's time was 9.5 minutes, while Biffi's was 7 to 10 minutes. A study of the published results according to various methods emphasized the following facts: First, that in each individual disease the maximum and minimum figures usually showed a wide variation. A second noteworthy fact was that the various diseases showed average differences which could hardly be considered of any real importance. They emphasized the fact that the average figures showed much less variation than those for the individual. Finally they found rather more than the usual disagreement in the results of different observers. Allowing for the personal factor and the difference in technique and method, the inconsistencies still appeared to be unduly suspicious. If these objections were valid in regard to adults their work had proved them to be equally true in the case of the child, with the added disadvantage that the examination of the coagulability of blood in children was attended with increased difficulties. It seemed to them that future efforts should be directed toward solving the problem of blood coagulability *per se*, or to a study of coagulability according to the more advanced standards, that was, the determination of the presence or absence, increase or diminution, in one or more of the various elements concerned in the formation of thrombin and in the latter's action upon fibrinogen.

Dr. Alfred Hand, Jr., of Philadelphia asked if studies of this nature had been made in typhoid fever and pneumonia. In both of these diseases there was quite a considerable formation of fibrin which caused a more or less plastic state of the blood, and this might explain the beneficial effects of drugs used in lessening the plastic state of the blood.

Dr. J. P. Crozer Griffith of Philadelphia said that nose and throat men emphasized the influence of certain agents upon the coagulability of the blood which seemed to aid them in their operative work; he felt skeptical on this point.

Dr. Howard C. Carpenter of Philadelphia, in closing the discussion, said that the coagulation of the blood in cases of broncho-pneumonia was practically normal, but it would be a mistake to draw conclusions from such a limited number of cases.

A Brief Report of an Epidemic of Sore Throat, with Involvement of the Cervical Lymph Nodes.—Dr. John Ruhräh of Baltimore made this report, in which he first referred to the epidemics of a similar nature which had occurred in European cities, and in several cities in this country in recent years. The epidemic in Baltimore began early in January and the cases increased in number and in the third and fourth weeks in February became very numerous. After the first three weeks of March there were very few of the typical cases noted. The Baltimore epidemic differed somewhat from other epidemics in that children were very largely affected, fully 50 per cent. of the cases occurring in early childhood. The organism, frequently in pure culture, which was seen in smears made from these cases, was a diplococcus with a distinct capsule, easily demonstrable with the usual capsular stains. It was Gram positive. The thermal death point in milk was 54° C. at an exposure of twenty minutes. The writer described the symptoms of four classes of cases: those of mild type, those of average severity, those of severe type, and those of unusual intensity; the last being usually due to some severe complication occurring at the onset. The complications attending the disease were remarkable for their number and intensity. The most common complication was inflammation of the middle ear, which occurred in from 30 to 40 per cent. of the cases. Next to this were irregular swellings, which rarely went to suppuration. They learned from this epidemic that a streptococcus infection might be caused by infected milk and that the disease might be very severe and attended with numerous complications and fatalities. They found that even in cold

weather milk might be the source of disease and that no matter how carefully raw milk was handled it might at times be a source of danger. The moral was that all milk should be pasteurized.

Dr. L. Emmett Holt of New York asked Dr. Adams whether he could tell how the infection got into the milk and what was the condition of the employees.

Dr. Charles Gilmore Kerley of New York said the case that had been reported interested him, as he had had a similar one. The child first had redness of the throat and swelling of the glands. This was followed by a mild pneumonia and the child was making a good recovery when a severe peritonitis developed. These symptoms subsided, when an acute nephritis supervened. Urinary suppression lasted for twenty-four hours, and when this condition improved the peritonitis returned and the child finally died after an illness of about four weeks.

Dr. Samuel McClintock Hamill of Philadelphia said that he understood that the final subsidence of the disease was due to repasteurization of the milk from the infected dairy, and he would like to know to what the preliminary fall was due, the one that occurred in March. He also asked if the milk was collected from a large number of farms and if there was any disease manifested among the cattle on the farms. With regard to the cream the committee appointed by this Association had created a standard for certification which could be relied upon.

Dr. J. H. Mason Knox, Jr., of Baltimore said he wished to speak regarding erysipelas as a complication of this disease. He had seen two fatal cases thus complicated. In both there was a little reddening of the throat, but there were no bubos. In another case there were two swollen reddened areas with points standing from three to four cm. from the surface. The erysipelas did not spread in this case and the child made a good recovery. In still another case, accompanied by high temperature, there were marked bubos and otitis media. They were also concerned as to the possible presence of peritonitis. The child made a recovery, went to Atlantic City, and after a few days developed scarlet fever, the rash lasting only four or five days. He would like to know whether any one else had had such an experience.

Dr. Fritz B. Talbot of Boston reported a case coming under his observation which a member of the Board of Health diagnosed as a diplococcus infection. There was a curious coincidence here. During the previous two summers there had occurred the same form of bacillary dysentery, but during the last summer there was a streptococcic infection of the gastrointestinal tract. A large number of babies developed pyelitis and in the majority of these the pure culture of the streptococcus was isolated from the urine.

Dr. Frank Churchill of Chicago said they were having a similar epidemic in Chicago, which was being carefully studied. He could not say how far this study had progressed, but the epidemic could not be attributed entirely to one dairy. The infection was severe and attacked many doctors. In all cases the streptococci were found.

Dr. John Lovett Morse of Boston said they had had two similar epidemics in Boston, one in the spring of 1911, which was very severe, and one this last Winter. The striking feature of the Boston epidemic was not the severity of the original infection, but that of the complications, such as endocarditis and general peritonitis. The latter cases were almost invariably fatal. Suppuration occurred in only a small proportion of the cases, but when it did occur it was deep and affected one gland after another.

Dr. John Ruräh of Baltimore, in closing the discussion, said that he could not say how the infection got into the milk; there had been considerable investigation, but they could not determine this point. In England it had been found that the infection originated from abscesses or diseased conditions about the mammary gland. The fall in the number of cases he thought was more apparent than real; it probably occurred in children who had had the disease. He had seen children with a rash strongly suggestive, but not typical, of scarlet fever. It faded away more quickly than the scarlet fever rash. He could not state as yet whether the organism was a streptococcus or a diplococcus. Dr. McCleary had studied a number of cases and had the idea that the organism was a pneumococcus. In nearly all the cases there was a combination of the streptococcus and pneumococcus. As to the treatment Dr. Ruhräh said the therapeutics used had been very unsatisfactory. When the temperature had been high, hydrotherapy had been employed and in some cases was followed by a rapid and marked drop in the temperature, while in other cases no measures seemed to have any effect. No vaccines had been used so far as he knew.

Inclusion Bodies in Scarlet Fever as a Means of Differential Diagnosis.—Dr. Matthias Nicoll, Jr., of New York read this paper, the abstract of which appeared in the report of the Section on Pediatrics of the New York Academy of Medicine, published in the Medical Record May 11, 1912.

Dr. Charles Gilmore Kerley of New York said that some four years ago two children came down on the same day with a rash like that of scarlet fever but very atypical. He sent slides to Dr. Nicoll for examination and one was reported positive and the other negative. In the case reported positive the rash disappeared in several days and the child desquammated, while in the case reported negative there were no signs of scarlet fever and the child did not desquamate. Dr. Nicoll had given them a very valuable aid in the differentiation of these obscure cases when there was a rash and yet it was impossible to tell from the clinical standpoint whether the case was one of scarlet fever or not.

Dr. Butterworth said he wished to relate his experience with yellow fever. He was sent to Vera Cruz to study that disease and after three months' work on the blood of yellow fever patients he believed that he had found a body which promised to throw much light on the disease. Later he found that this body was only a yeast fungus, so he advised them to "go slow" in this matter.

Dr. Matthias Nicoll, Jr., of New York said they had made an attempt to find out how long these bodies would last, but they disappeared in from five to twenty-eight days. The cases which did not desquamate were unquestionably German measles. Dr. Nicoll said he did not understand what Dr. Butterworth meant. These inclusion bodies were there, and were not found in any other condition, so far as he knew, except in cases of sepsis. As to what the bodies were he could not say.

Studies in Metabolism of Amaurotic Idiocy—Dr. Henry Heiman, Dr. Samuel Bookman and Dr. Burrill B. Crohn of New York City presented this paper. They stated that the obscurity regarding the true nature of this disease was still as great as ever. As this condition was so prominently characterized by a marked and generalized degeneration of nerve cells and nerve tissue they thought it would be interesting to discover the chemical evidences in the excretions of the degenerative process which they knew to be going on. This should be evidenced by some disturbance in the excretion of those elements which were so largely an integral part of nerve tissue, namely, phosphorus and sulphur. The first case studied was that of a child fifteen months of age; the second case was that of a child seven months of age. Histories of these cases were presented and tables showing the daily average intake and output of nitrogen, sulphur, phosphorus, and chlorine, also tables showing the average daily retention percentage of intake and the absorption percentage of intake. The data showed the fact that absorption from the gastrointestinal tract and retention within the body were normal or even better than normal for all constituents determined. There was no marked disturbance for the intake and output of phosphorus and sulphur. The good absorption and retention probably indicated a hypernormal anabolic function occurring at a certain stage of the disease. When one took into account the very slow process of degeneration and the very small amount of actual phosphorus and sulphur in the entire cerebrospinal system one could understand why the daily elimination of these constituents would fail to be manifested during a short period. It would be advisable to study the disease at intervals during its course, both in the earlier stages where anabolic changes predominated and in the later stage where degenerative and catabolic process played an important part.

Congenital Obstruction of the Posterior Urethra.—Dr. J. H. Mason Knox, Jr., and Dr. Thomas J. Spruit of Baltimore reported this case. The patient was a boy, five years of age, who had had difficulty in controlling micturition from infancy. Urination occurred every half-hour day and night and was attended with no pain. Four weeks before death there occurred a sudden onset of the terminal illness with cough, abdominal pain, vomiting, and constipation. There was a tumor above the symphysis with a dull percussion note. There were also a redundant foreskin and phimosis. The patient was circumcised three weeks before death with the result of slightly improving the flow of urine. All attempts at catheterization failed. At autopsy an obstruction was found in the prostatic portion of the urethra, which was converted into a blind pouch by the fusion of its anterior and posterior walls, due apparently to an overdevelopment of folds normally present immediately distal to the verumontanum. A small triangular opening in the floor of this pouch, whose sides meas-

ured three millimeters, was the only communication with the anterior urethra. As a result there was marked dilatation and hypertrophy of the bladder, ureters, and kidney pelves, with a typical hydronephrosis terminating in uremia. They had been unable to find a similar case reported in American literature. The condition, if recognized, could be easily corrected.

Typhoid Fever in Infancy.—Dr. J. P. Crozer Griffith of Philadelphia presented this communication which consisted of an analysis of 73 cases, more than half of which had come under his own observation. This was the largest series yet published. The age limit had been fixed at two and one-half years. The statement was incorrect that typhoid fever in infancy occurred only or chiefly in family epidemics, since 78 per cent. of his cases occurred singly. The onset of typhoid fever in infancy was of decidedly shorter duration than later, the length averaging perhaps three or four days before evidence of the fully developed attack was present. The attack usually developed rapidly and was often sudden, only about one-third of the cases showing a slower appearance of symptoms. These symptoms consisted chiefly of fever, diarrhea, vomiting, prostration, headache, loss of appetite, cough in certain cases, fretfulness, and abdominal pain. Vomiting was a symptom seen decidedly more frequently than later and loss of appetite was often observed. Prostration was seldom marked. Cough and pain were infrequent and epistaxis was rare. Decided loss of appetite was uncommon. Abdominal distention was frequent, probably more so than at later periods of childhood, but was seldom distressing. Bronchitis was common. The heart and pulse were seldom much involved. The nervous symptoms, on the whole, were not marked. The course of the temperature was uncharacteristic. The complications in their order of frequency were diphtheria, pneumonia, otitis, furunculosis, measles, ulcerous stomatitis, ischiorectal abscess, parotitis, jaundice, pertussis, intestinal hemorrhage, conjunctivitis. A decided tendency to suppurative processes was seen in 18 cases. There were three relapses, possibly four. In 61 cases the diagnosis was based on the Widal test. The treatment was entirely symptomatic.

Dr. Alfred Hand of Philadelphia asked Dr. Griffith if he had attempted to classify the cases so as to tell which were under one and which under two years of age. The conclusions of Dr. Griffith bore out his own experience. The average duration of these cases did not differ so much from that in older children. The cases of long duration were those with a low temperature, from 101° to 102.5°. The diagnosis of typhoid fever in infants was as easy by the Widal test as in adults and he thought the test more valuable in infants than in adults, as in the latter there was a greater possibility of the patients' having had the disease before. Dr. Hand thought that a mortality of 16 per cent. was very high. Sometimes the initial infection was severe and the mortality rate went up in consequence. He could not recall one instance of nosebleed in an infant. As a rule the diagnosis was comparatively easy and the Widal test merely confirmed the diagnosis. It should be used far more frequently than it was in infants, as the disease was not recognized as often as it should be. Typhoid fever was not as prevalent in the Philadelphia hospitals as it was formerly.

Dr. John Lovett Morse of Boston said that Dr. Griffith's paper had covered the ground very thoroughly. While his experience had not been as large as Dr. Griffith's he agreed with him in regard to the sudden onset, the quicker fall of temperature and the greater severity and mortality of the disease. It seemed to him that the cases he had seen did not require the Widal test to make a diagnosis. The existence of leucopenia was a diagnostic aid.

Dr. Charles Gilmore Kerley of New York asked how these infants were fed.

Dr. Griffith replied that he could not make an exact answer, but they were mostly on milk diet, with sometimes the addition of broths.

Dr. Kerley said that the only way and the best way to bring up the mortality was to feed these children with milk. In twenty-four years' active practice among children he had learned that milk was absolutely contraindicated in typhoid fever.

Dr. Edwin E. Graham of Philadelphia said that his experience with typhoid fever in infants corresponded largely with what Dr. Griffith had stated, but he differed in two particulars. He had always believed that the mortality in early childhood was comparatively low, something below 16 per cent. Dr. Graham recalled the time when the hospitals were filled with typhoid cases and said that in a certain hospital which was formerly filled with typhoid fever cases they had not had a single case during the past year. However, he had recently seen three cases in Philadelphia due to house infection. Children should be garded against such infection which occurred through personal contact.

Dr. Fritz B. Talbot of Boston reported a case of typhoid fever in an infant resulting from mother's milk; the milk showed living typhoid bacilli. He asked Dr. Griffith if any of his babies were breast fed and if it was a common thing for infants nursing from the breast of a woman with typhoid fever to contract the disease.

Dr. Henry Heiman of New York said he had found it rather difficult to make a diagnosis in typhoid fever in children unless they were in the midst of an epidemic. He made it a practice to have the Widal test made in suspicious cases. It was extremely difficult to get blood cultures in young infants; probably in time they would have an improved technique which would enable them to do so.

Dr. Samuel Adams of Washington said that he had called attention to the prevalence of typhoid fever among infants some years ago and that its frequency was a fact not generally recognized at that time. So far as mortality was concerned he wished to repeat what Dr. Osler had said, that they should remember that they were dealing with hospital cases. There was a marked difference between hospital cases and those in private practice. With regard to the Widal reaction and blood culture he was glad to hear what Dr. Heiman had said. In one epidemic of typhoid fever he had tried to get assistants and had the best in the country, but they hesitated to take chances in attempting to get blood cultures in children under seven months of age. His experience was similar to that of Dr. Hand in that they had much less typhoid fever than formerly; they had difficulty in getting enough cases to demonstrate before a class of 75 students. Dr. Adams greed with the other speakers in regard to the question of diagnosis, that it was not always a difficult matter to make a diagnosis during an epidemic or when it resulted from house infection. The symptoms often presented themselves in such a way that little difficulty was encountered in making a diagnosis even in the early stages of the disease. He had often made a diagnosis from the general appearance of the patient and the history given by the parents.

Dr. Henry C. Coit of Newark, N. J., asked Dr. Griffith if, in his experience with reports from laboratories, he had received reports of positive Widal reactions in cases that presented no acute symptoms. This had occurred in his own experience and it raised the question of the possibility of a baby being a typhoid carrier.

Dr. J. P. Crozer Griffith of Philadelphia, in closing the discussion, said that, in answer to Dr. Hand's question, 60 per cent. of the babies were two years of age or less. Long-continued fever was less frequent than in older children in his experience. Regarding the occurrence of bronchitis he stated that it occurred in at least 47 per cent. of the cases; it occurred so commonly that it should be called a symptom and not a complication. He did not think it necessary to make blood cultures in infants. The Widal test was only made as a final test. The leucocyte count was higher in infants than in adults. None of the children in his series were breastfed. He could not agree with Dr. Kerley that the mortality was due to the milk; he believed that it was more often due to complications. If milk had a deleterious effect in children it should have the same effect in older children. In his series of 75 cases only 16 could be traced to house infection. The Widal test was made in every child supposed to have the disease, but not in those children who gave positive symptoms.

(*To be continued.*)

Osteitis Deformans with Chronic Eczema.—F. Parkes Weber reports the case of a compositor, aged 70, who presented the typical thickening and bending of the tibiæ and femora characteristic of osteitis deformans. The disease was as yet of only moderate degree, and was limited to his lower extremities. The changes commenced, or at least were first observed, in the left tibia six years ago, and at present they were best marked in that bone and the left femur. The eczema, to which he had been subject more or less for many years, at present chiefly affected his legs. On the whole the patient seemed to have enjoyed good general health, but had suffered twice from rheumatic fever, forty and twenty-four years ago, respectively. There was no history of any venereal disease. Nothing abnormal could be discovered in the thoracic or abdominal viscera or in the urine. A noteworthy feature of the present case was that as yet there had been no pain connected with the bone disease.—*Proceedings of the Royal Society of Medicine.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 27, 1912.

The President, Dr. Charles Gilmore Kerley, in the Chair.

Executive Session.—Injunction Served.—Announcement had been made that a new vote would be taken at this meeting on the motion to adopt the report of the Comitia Minora recommending that Dr. Robert Kuhitzer be expelled from membership in the Medical Society of the County of New York, but when the members arrived a temporary injunction from Supreme Court Justice Blanchard was found posted forbidding further action in the matter.

Report of Committee on Dispensary Abuse.—This committee reported progress in its work of investigation and invited the cooperation of individual members of the society with the committee by furnishing the names and addresses of individuals who, to their personal knowledge, had unworthily received dispensary treatment. Such information would not be made public or used as the basis for information without the approval of the donor. Such names and addresses should be sent to Dr. William S. Thomas, 240 West Seventy-first street, New York City.

Certified Pharmacies.—A resolution was passed calling for the appointment of a committee of ten to confer with the American Pharmaceutical Association on the subject of certifying pharmacies in the same way that dairies are now certified.

Resolutions on the Death of Dr. Samuel Oakley Vanderpoel.—The following resolutions were passed by the society: *Whereas*, death has suddenly removed from our membership Dr. Samuel Oakley Vanderpoel, and *whereas*, Dr. Vanderpoel during his period of activity gave unsparingly of his time and energy in furthering the interests of our organization, never considering any task too great or labor too arduous and exacting to call for his best efforts, and *whereas*, Dr. Vanderpoel served the society as president from October, 1898, to October, 1899, and as a censor during the following year, and *whereas*, throughout his entire professional life he portrayed the high ideals of the true physician, and *whereas*, in his death we have lost a true friend, a faithful worker, and a respected counsellor; therefore, be it *resolved*, that the Medical Society of the County of New York, through its proper officers, express its deep sense of sorrow in the death of Dr. Samuel Oakley Vanderpoel, and that we extend to his bereaved family our sincere sympathy. *Resolved*, that these resolutions be spread upon the minutes of the society and a copy forwarded to his family. (Signed) Wendell C. Phillips, Frank Van Fleet, Charles N. Dowd.

Tuberculin Diagnosis and Therapy.—Dr. James Alexander Miller read this paper, in which he described the different varieties of tuberculins and the methods of their preparation. He stated that the active principle in all these tuberculins was the same and this principle was the bacillary proteid contained in solution. The clinical action of the different varieties was also similar. Many theories had been advanced to account for this action, but at present there were two that were deserving of attention, the Wolff-Eisner lysin theory and that of the histogenous hypersensitiveness. Dr. Miller then considered the reaction to tuberculin in respect to the specific, local, or focal reaction; and the general reaction, as shown by congestion, by its effect on the leucocyte count, and on general metabolism. As a diagnostic agent tuberculin had been administered by the following methods: Cutaneous, subcutaneous, intracutaneous, percutaneous, and conjunctival. The nature of the reaction was the same in all of these methods. The conjunctival method was dangerous and had been practically abandoned. Small doses of tuberculin produced a reaction only in the newborn and a very few adults. A reaction in healthy persons might be due to an overdose of tuberculin or direct toxicity, to the abnormal presence of lysin, or to an inactive lesion with the lysin persisting. The absence of reaction in positive cases might be due to the fact that in slight inactive cases little lysin was present and its activity was gone, or to the fact that the tissue damage was so great that lysin could not be produced, or because the lysin was neutralized by active tubercle bacilli so that there was no free lysin. As to the value of the subcutaneous test, each year they were going down in their conception of the dose; two or three milligrams was formerly considered the maximum dose, while now one milligram was as high as it was considered advisable to go. They now used small doses up to 0.0009 mg. Practically all adults reacted to the cutaneous test, but there was valuable information to be obtained from the time of the response. If the process was slight, the reaction might be delayed. The tuberculin test as a help in diagnosis was used less than formerly, but the diagnosis of tuberculosis could not always be made easily and it was often a valuable help. In regard to tuberculin therapy two methods had been used; first, that of small doses not increased, the reaction being judged by the opsonic index. This was the method used by Wright in England. The second method was based on tuberculin tolerance without reaction. If tuberculin was used the general condition of the patient must be good. In general, cases having fever should not be subjected to the tuberculin treatment. The chief value of the tuberculin was in chronic advanced lesions with occasional exacerbations. The extent of the lesion was no indication as to whether tuberculin should be used or not. In regulating the doses each patient was a law unto himself. No harm could be done by going too slowly and much harm might be done by going too rapidly. The administration of 0.0001 mgm. would show the sensitiveness of the patient. As much benefit was often obtained from a small dose as from a larger one. One should keep below the reaction but not too far below. The guides to the dosage were the local, focal, and general reaction. The local reaction should not last longer than twenty-four hours. The focal reaction was indicated by increased cough and expectoration, and when this was noted one should be careful and not give the doses so close together. The reaction should never go to the point of producing fever. Other guides were the opsonic index and the leucocyte count, but these were not delicate enough. Progressive dosage might be made on the decimal system or on double strength solutions. In case of reaction one should go back to the third previous dose. It was usually necessary to continue the treatment for from six months to one year. In chronic cases it might be necessary to take a second course. He usually began with 0.001 mg. and if there was no reaction doubled the dose at the end of the week. The results of the treatment were most marked in the constitutional symptoms. In the course of four or five months the patients lost the sense of fatigue, the cough, etc. These results had been seen in some instances in four weeks. Some of the specific results noted were that the patients cured by this method kept well longer, the relief of toxic symptoms were most marked, and a considerable percentage of the patients lost the bacilli. The influence of the tuberculin on the physical signs in advanced cases was often very slight. The results were best gauged by clinical evidence and while tuberculin was a valuable adjunct in suitable cases if properly given, it was simply an aid like digitalis in heart disease. It did not produce true immunity.

An Experimental Study of a New Remedial Agent and Its Effects in Pulmonary Tuberculosis.—Dr. Bertram H. Waters presented this study. He first reviewed the literature of inhalation therapy, which showed that from the earliest times the subject had held an important place. This history also showed that doubt had never been expressed of the penetration of gases, either pure or combined with remedial substances, into the lung, and even into the blood stream. The substances which had given the best results thus far were oxygen, ozone, and the ethereal oils and balsams; among the latter the turpenes had been used with considerable success. To this latter class belonged turpentine, the complex essential oil of the pine tree, and this study dealt with its chief constituent, pinene. To it were attributed the physiological and therapeutic action of oil of turpentine, which was but slightly toxic and was a cardiac stimulant and a general stimulant to mucous membranes. Before describing this new method, Dr. Waters said he wished to state that no attempt had been made to put these generators on the market and it was intended, not to sell them, but to lease them to physicians of established reputation, or through them to their patients, reserving the right to withdraw them for any misuse of the method or false statement of its value. There would be no exploitation of a "cure all" but a dignified and ethical presentation of a valuable remedial agent. The method was as follows: By means of a highly perfected ozonizer, and an apparatus which effected a chemical combination of ozone of pure quality with pinene, the base of pure rectified oil of turpentine, a gaseous pinene ozonide was produced, named "terpezone," which had a high oxygen efficiency, yet which was easily respirable. This generator thus produced two of those substances which had already given some evidence of their therapeutic value, in a much safer and more practical form. Terpezone contained no free ozone. The air stream upon which the ozonizer acted and that which was in contact with the oil of turpentine was chemically dry. In this

combination none of the well-known oxidizing and germicidal properties of the ozone were lost, while the pinene made it easily and pleasantly respirable and produced the therapeutic effects of that oil. The apparatus which Dr. Waters described and illustrated by photographs was simple, not at all cumbersome, and could be employed without special preparation or the use of a cabinet involving change of atmospheric pressure. In order to determine the chemical action and nature of terpezone a chemical investigation had been carried out in the laboratory of Columbia University with the assistance of Dr. J. M. Nelson. These experiments, while of too technical a nature to detail, demonstrated conclusively that the substance was an entirely new one, namely, a gaseous pinene ozonide, in which the infinitely minute particles, or molecules were in suspension, in the form of a gas, which, being anhydrous, could not properly be called a vapor. As to the chemical nature of the substance, it might be said that ozonides in general all underwent decomposition more or less readily, forming aldehyde and acid groups at the position of the original double band, and also giving off nascent oxygen. Experiments made in the laboratories of the University and Bellevue Hospital Medical School had shown that for typhoid, diphtheria, colon, staphylococcus, subtilis, and anthrax in pure broth culture, even when the lightest moisture was present, terpezone was germicidal, in the room atmosphere, in twenty-five minutes to two and one-half hours. Clinical observations had been made on twenty-one patients. After giving a detailed account of these observations the essayist said they seemed to indicate that: (1) The percentage of hemoglobin was increased under this treatment and the increase did not seem to depend upon the administration of iron. (2) The erythrocytes increased, at least temporarily, irrespective of the severity of the lesion. (3) When marked leucocytosis existed, due to toxemia, it was reduced. When the number of leucocytes was below normal, it was increased by treatment. (4) The lymphocytes were increased and remained so in those patients who improved. It seemed probable that this increase might be considered as a reliable indication from the prognostic standpoint. (5) The large mononuclears seemed to follow the curve of the lymphocytes. Their increase or decrease might have a like significance. (6) No conclusion could be drawn from the behavior of the transitionals, eosinophiles, or basophiles. There seemed to be under this method of treatment, temporarily at least, even in the progressive types of the disease, a distinct and constant tendency of the cellular elements of the blood and the hemoglobin to approach their normal ratios. The most immediate and noticeable effect of treatment was relief of the dry, ineffectual cough. This seemed to be due to the effect upon the sputum, which was increased in amount and rendered more liquid, so that it was raised with much less difficulty. In all cases the complicating bronchitis was relieved or disappeared entirely. There was a marked diminution of tubercle bacilli and the secondary organisms in the sputum, and in some instances they were absent on several successive examinations. The temperature, pulse, and respiration of those patients who presented any hope of improvement were reduced and steadied. In no instance was acceleration of respiration observed. In those patients who improved there was a noticeable diminution of toxemia, indicated by the less frequent occurrence or disappearance of rigors and hyperhydrosis. The amount of urine and the excretion of urea were increased. The appetite was in no instance impaired, but rather seemed to be improved. Sleep was more continuous, sound, and more refreshing. At no time was there any evidence of irritation of the heart, lungs, or kidneys, except when an inferior quality of turpentine was used. The weight increased and the improvement both of the general condition and of the pulmonary lesions seemed to be as rapid and satisfactory, and to compare favorably with that obtained under sanatorium care. It was noticeable that all of the patients who were treated in the city made quite as rapid progress here as afterwards in the country. These results seemed to depend upon the action of terpezone as a stimulating expectorant; in increasing the protective cellular elements of the blood and correcting the secondary anemia, thus raising the resistance of the individual; in increasing the oxygenation of the blood, thus influencing metabolism and stimulating the excretion of waste products; in diminishing toxemia. This agent, through its efficiency as a germicide and its respirability, might be of special value in surface infection of the mucous membrane such as tonsillitis and influenza, possibly also diphtheria and scarlet fever. It was probable, though further evidence of this action was required, that by reason of its high oxidizing efficiency, and the liberation of nascent oxygen, it might have a neutralizing effect upon pathogenic organisms, and toxic substances in the blood stream. If this should be demonstrated, its field of usefulness could be greatly enlarged.

The Practical Physical Diagnosis of Early Pulmonary Tuberculosis.—Dr. S. Adolphus Knopf gave a demonstration on the living subject of his method of making a diagnosis of early tuberculosis. He said that upon seeing the patient for the first time the first thing one should do was to ascertain the social condition of the patient, his employment, how many windows he had in his bedroom, etc. One should remember that the family history was not as important as tradition, unconsciously to the physician, was apt to make it seem. On the other hand it was very important to find out how many brothers and sisters the patient had. The younger children in large families were much more susceptible to tuberculosis than the older ones. The younger children in large families usually did not receive the same careful watchfulness nor the same amount of nutrition. In young girls one should inquire carefully into the menstrual history. A diminution in the amount of menstrual fluid was one of the signs of early tuberculosis. Then one should begin the physical examination at the head. In early tuberculosis the hair was apt to be dry and brittle. The eyes should be carefully examined and any irregularity in the pupils noted. The upper respiratory tract should receive special attention, for it was useless to try to treat the lungs if the upper air tract was diseased. Nervous irritability and loss of appetite should be taken into consideration. Possibly the patient slept badly and complained of pain. This might occur anywhere and might bear no direct relation to the localization of the disease. In examining the mouth one should look for a reddish line on the gums; while this might not be pathognomonic of tuberculosis it was a valuable sign taken in connection with other symptoms. If the mucous membrane of the mouth and upper air passages was pale it should be regarded as a suspicious sign. One should then have the patient inhale and exhale and watch the movement; generally it was impaired either longitudinally or laterally. One should next palpate for fremitus. It was a good thing to have the patient hum; this often revealed a consolidation that had passed unnoticed for years. By placing the hand over the part and then touching the forehead to the back of the hand it was surprising how much one could hear. In testing for fremitus one should not use both hands at the same time unless certain that they were equally developed as to sensibility. In speaking of percussion Dr. Knopf said that the finger was the best percussor and every portion of the chest should be percussed. The patient should be instructed to hold his hands over his head during percussion. The ear should be used first and then the stethoscope. Dr. Knopf then considered auscultation, calling special attention to the value of expiration in revealing râles. He thought that such a systematic examination with careful observation of the signs would save many lives, and it was quite possible for the general practitioner to make this examination provided he would take the time.

Dr. Hermann M. Biggs said that he thought that Dr. Miller had put the subject of tuberculin in about the right light. In administering tuberculin he began with 0.001 mgm. of old tuberculin, and if there was no reaction or only a slight increase in cough and expectoration, he doubled the dose at the end of one week, and he continued to double the dose each week so long as there was no reaction until 10 milligrams were given; he then used a solution of 1 c.c. to 1000, increasing the dose by one quarter each week. The results on the whole were satisfactory. Advanced cases that showed no reaction did better with tuberculin than without it. The Health Department did not compel patients to subject themselves to the tuberculin treatment, but made the matter one of choice. If the patient reacted to the dose he went back to the third previous dose and increased it one-third. Dr. Biggs said he could not quite agree with the statement Dr. Knopf had made that the diagnosis of early tuberculosis was an easy matter. There were many cases which did not produce signs or symptoms upon which one could base a diagnosis. Where there were no physical signs it was only a matter of experience and judgment and men of equal ability would arrive at very different opinions, and would express different opinions on a given case at different times. There were a large number of cases in which it was impossible to say definitely that incipient tuberculosis was present; the only way to do was to keep these cases under observation and await the outcome.

Dr. Theodore C. Janeway said that in making a diagnosis of tuberculosis there were two things to keep in mind, namely, what were the symptoms of tuberculosis and what other diseases might give rise to similar symp-

toms. He cited the case of one patient whom he had watched from October to May without being able to find any abnormal physical signs; then he found a few crackles; a month later these were more pronounced. After that the patient began to improve and made a good recovery and was still in good health after twelve years. One might be biased by the history without having adequate physical signs. Other diseases that produced similar symptoms were the chronic type of infective endocarditis; hyperthyroidism, it being possible for tuberculosis and hyperthyroidism to be coincidental; certain syphilitic conditions, which were rare; pleural effusions, in which he did not dare make a differential diagnosis. It was always risky to make a diagnosis of tuberculous peritonitis in anyone but a child; he made it a rule to change that diagnosis to carcinoma and found that he was frequently right. In auscultation he had found that the diseased portions of a lung were often cut off from ordinary respiration and the signs that one obtained were from the healthy part of the lung. Sometimes a patient had to walk for fifteen minutes before it was possible to obtain signs and then one might find disseminated tuberculosis of the entire lung which he had overlooked before.

Dr. Ephraim D. Klotz said he would confine his remarks to the method described by Dr. Waters. In the Metropolitan Hospital they had a ward of eighteen beds where they had installed five generators. After these were in operation for a few minutes they charged the air with a substance that looked like smoke and had an odor similar to that of a newly painted room. The nurses and internes said that it caused a slight conjunctivitis and slight constriction of the chest both of which soon passed off. Observations on patients in this ward showed that there was marked improvement in the blood count and an inclination for the blood to assume a normal relation between the cells. They had been warned that they might expect kidney troubles on account of the turpentine, but there had been no case of albumin, or any apparent disease of the kidneys. In a large proportion of the cases there was an increase in the total output of urine. Twelve out of sixteen patients still retained the tubercle bacilli and the volume of sputum had been diminished; in four it had remained the same. The weight increased in eight cases out of sixteen. In most of the cases the cough was less at night and the patients got up feeling better in the morning. There were two deaths in the series within ten days from the time of beginning treatment; one in a patient having extensive involvement of both lungs, pneumonia, miliary tuberculosis and enlarged liver and the other case, in which no autopsy could be obtained, had symptoms of pneumonia.

Dr. Beverley Robinson said that the general medical profession felt uncertain as to the value of tuberculin. He did not use it and what he had seen of it did not impress him very favorably. However, he thought Dr. Waters had done good work. As to physical diagnosis he wished to corroborate what Dr. Biggs and Dr. Janeway had said. Many hospital physicians found it difficult to make a diagnosis in spite of a great deal of careful examination by all improved modern methods. Yet, personally, as he left the wards after witnessing these efforts he could not help thinking "What's the use of all this; are the people any better off?" The conviction kept growing upon him that there was no specific for tuberculosis and never would be. Since he had studied medicine he had never seen two patients alike and one had to think out each individual case. As to treatment, Dr. Austin Flint's thesis written twenty-five or thirty years ago was still well worth reading. A certain proportion of the cases of tuberculosis would get well anywhere, with bad air, insufficient food, etc., while others would die no matter what was done for them.

Dr. A. Alexander Smith said he, too, endorsed what Dr. Biggs and Dr. Janeway had said; it was not always easy to diagnose early tuberculosis through physical signs. Oftentimes the physical signs were very numerous when the lesion was very slight; at other times there might be an enormous amount of disease and freedom from physical signs. A localized and circumscribed area of subcrepitant râles was a sign more than suspicious if accompanied with signs of consolidation. This statement had to be modified in the presence of the influenza bacilli; he had found that these caused a circumscribed area of râles which would clear up and now he was very conservative in making a diagnosis on this basis. It was very important in making an examination to ask the patient to cough. One should also remember that other structures were involved primarily beside the apex. The process did not necessarily commence at the apex in the right intrascapular space. Dr. Smith called special attention to the value of the whispered voice.

Dr. Mark I. Knapp said that he had arrived at the conclusion that when there were no physical signs one dared not make a diagnosis of tuberculosis and when there were these signs it was too late. In records of St. Bartholomew's Clinic he had observed invariably that when there was a condition of budding, sporating yeast in the stomach together with insufficiency of the pylorus and slight physical signs it was safe to make a diagnosis of tuberculosis.

Dr. James Alexander Miller, in closing the discussion, said that his statement that a positive cutaneous reaction could be obtained in all adults had been questioned, but he wished to repeat that this was true of 95 per cent. of adult persons. The reason was that nearly everyone had been exposed to the tubercle bacilli before reaching the age of five years.

Dr. S. Adolphus Knopf said he was glad he had made the remarks in regard to diagnosis which had brought out discussion. He said he quite agreed that in many cases the making of a diagnosis was by no means easy. He had neglected to speak of temperature; the temperature should be taken, not once, but several times. The patient should be made to exercise and then the temperature should be taken. If the general practitioner gave as much as three quarters of an hour, as he himself was accustomed to doing, to an examination, he could make as good a diagnosis as the specialist. In the presence of physical signs always put the patient on treatment for tuberculosis; if he had the disease it might do him good and if he did not have it no harm was done.

Pathological Society of Philadelphia.

At a stated meeting held May 9 Drs. O. H. Perry Pepper and D. L. Eastland presented specimens of "Coincident Aneurysm of the Aorta and Empyema." The patient exhibited percussion-dulness over the greater portion of the left side of the chest, with suppressed breath-sounds and dimished vocal resonance and fremitus. The pupils were unequal, the voice high pitched and there was a brassy cough. Puncture disclosed the presence of pus in the left pleural cavity and resection of a portion of a rib resulted in the evacuation of a small amount of pus. The condition of the patient grew gradually worse until death ensued. On post-mortem examination the left pleural cavity was found partly obliterated, and partly forming a cavity containing pus and blood. The descending aorta was dilated in its first portion and at a lower level the seat of a sacculated aneurysm, whose rupture had brought about the fatal result. Dr. Robert A. Keilty presented a specimen of "Chronic Pericarditis with Calcification," and one of "Tuberculous Pericarditis." Drs. Moses Behrend and Henry Wise presented specimens of "Embolism and Thrombosis of the Popliteal Artery in a Case of Mitral Stenosis, Followed by Gangrene of the Leg and Foot." The patient was a man, 36 years old, with physical signs of mitral obstruction, attended with copious hemoptysis, and who was seized with intense pain in the posterior aspect of one leg, together with symptoms simulating those of angina pectoris, and at a later period suffered a second attack with similarly intense pain involving the right leg. No evil results attributable to vascular obstruction were noticed in the left lower extremity, but in a short while the right leg began to undergo gangrene. On consultation amputation of this latter member was agreed upon and carried out. The wound was healing kindly and the patient appeared to be doing well, when a third attack of pain, affecting the left leg, developed, and death shortly followed. On post-mortem examination, obstructive thickening of the leaflets of the mitral valve was found, together with a fairly well organized thrombus in the left auricle. The femoral artery of the emputated member was occluded, the vessel being collapsed above and below the site of occlusion. The spleen was the seat of a hemorragic infarct. Dr. E. A. Case presented a specimen of "Aneurysm of the Coronary Artery." The organ was discovered in the dissecting room. The pericardial cavity contained blood and the source of which was found in a ruptured aneurysm of one coronary artery. A second aneurysm occupied a sinus of Valsalva. Drs. J. H. Austin and G. M. Peirsol presented a communication entitled "The Use of the Crehore Micrograph in Clinical and Experimental Studies of Cardiovascular Conditions." The results obtained were not satisfactory by reason of technical and other difficulties in the employment of the apparatus, which it was thought had no practical advantage over the Franck manometer. Drs. Austin and Peirsol also presented a communication entitled "Do the Two Vagi Differ in Their Control of the Heart Action?" The study was undertaken with a view of confirming or disproving the contention that has been made that the right vagus acts

especially on the auricles and the left on the ventricles. It was found in experiments on dogs that stimulation of the peripheral extremity of either cut vagus exerted equally no appreciable effect on the force and freqquency of either auricle and likewise none on the force of either ventricle, although stimulation of the left vagus in some instances induced a condition of heart-block. Dr. W. M. Late Coplin presented a communication entitled "Influence of Longitudinal Stress on the Collapsibility of Vessels."

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Handbuch der speziellen Chirurgie des Ohres und der Oberen Luftwege. Vol. 1, Part 2, No. 6. By Drs. L. Katz, H. Preysing and F. Blumenfeld. 80 pages; illustrated; paper; price 4.50 M. Curt Kabitzsch, Publisher, Würzburg.

Schmidt's Jahrbucher der in und Auslandischen Gesammten. By Prof. D. H. Leo. Vol. 314, No. 4. 112 pages; paper; A. Marcus & E. Webers, Publishers, Bonn.

Uber Serodiagnostik und Serotherapie in der Augen Heilkunde. By Dr. Otto Kuffler. 56 pages; paper; Vol. 8, No. 6; price 8 M. Carl Marhold, Publisher, Halle.

Sixth Annual Report of the Henry Phipps Institute. 136 pages; paper. Henry Phipps Institute, Publishers, Philadelphia.

Primary Malignant Growths of the Lungs and Bronchi. By I. Adler, A.M., M.D. 325 pages; illustrated; cloth; price $4.00 net. Longmans, Green & Company, Publishers, New York.

Essays and Clinical Studies. By F. G. Crookshank, M.D. 245 pages; cloth; price 7/6 net. H. K. Lewis, Publisher, London.

Anglo-Saxon Leechcraft. An historical sketch of early English medicine. 262 pages; illustrated; cloth. Burroughs, Wellcome & Company, Publishers, New York.

Twenty-third Annual Report of the Derby Borough Asylum for the Year Ending December 31, 1911. 69 pages; paper. Derby Borough Asylum, Publishers, Derby.

Sewage Disposal. By George W. Fuller. 767 pages; illustrated; cloth; price $6.00. McGraw-Hill Book Company, Publishers, New York.

Kurzgefasste Anleitung zu den Wichtigeren Hygienischen Untersuchungen. By Dr. Bernhard Fischer. 270 pages; cloth; price 5.60 M. August Hirschwald, Publisher, Berlin.

Seventh Annual Report of the Board of Managers of the Manhattan State Hospital to the State Commission in Lunacy. For the year ending September 30, 1911. 147 pages; paper.

The Institution Quarterly. Vol. III, No. 1. Edited by A. L. Bowen. 215 pages; paper. The State Board of Administration, the State Charities Commission and the State Psychopathic Institute, Publishers, Illinois.

Acromegaly. By Leonard Portal Mark, M.D. 160 pages; illustrated; cloth; price 7/6 net. Bailliere, Tindall & Cox, Publishers, London.

Yearbook of the United States Department of Agriculture, 1911. 732 pages; illustrated; cloth. U. S. Department of Agriculture, Publishers, Washington.

Uber Kongenitale Syphilis, Entstehung, Erscheinungen und Behandlung. By Dr. Fr. Bering. 36 pages; paper; price 1.20 M. Carl Marhold, Publisher, Halle.

Uber die Behandlung der Gonorrhoe des Mannes. By Dr. V. Klingmuller. 36 pages; paper; price 1.00 M. Carl Marhold, Publisher, Halle.

Diagnostic Methods—Chemical, Bacteriological, and Microscopical. By Ralph W. Webster, M.D., Ph.D. Second Edition, revised and enlarged, with 37 colored plates and 164 other illustrations. 682 pages; cloth; price $4.50 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

Sarcoma of the Ilium Treated by Coley's Fluid.—A. Carless reports the case of a patient, aged 49, who was admitted to the hospital in October, 1909, and whose symptoms existed for eighteen months before that date. At first he complained of pain in the buttocks and calf, which were supposed to be sciatica, and the tumor was not noticed till just before his admission. It then extended from the right iliac fossa upwards as far as the rib margin and back to the spine, filling the right lumbar region. It was hard and immobile, fixed firmly to the innominate bone and to the lumbar spine. At first the pain was so severe that morphine was required, even when he lay in bed. Operation being hopeless, treatment by Coley's fluid was undertaken. When exhibited in February, 1910, his condition was much improved, the pain was absent, and the swelling had decreased in size. Since that date several courses of Coley's fluid have been administered, and the swelling has gradually shrunk, the patient being able to get about and complaining of no pain. Nothing has been undertaken in the shape of treatment for six or eight months.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 5, 1912:

A CASE OF STILL'S DISEASE.*

By V. P. GIBNEY, M.D.

NEW YORK.

MALE, aet. four years. Referred by Dr. Kurth of Schenectady, New York, and admitted to Hospital for Ruptured and Crippled January 19, 1912.

The doctor sent with the patient a very full history from the time of the child's birth, and from this I learn that when five weeks of age he had a very severe attack of gastroenteritis, the mother not having been able to nurse him, but under a change of diet he responded quite readily. Shortly afterwards he had whooping cough which proved to be a mild attack. At two years of age he had measles without any sequelæ. When 2½ years of age he had a fever which lasted six weeks, regarded as of malarial origin, but not responding to the usual remedies. He made a fine recovery later and was strong and hearty, as shown by the accompanying photograph, Fig. 1.

His present illness dates from January 14, 1911, when he complained that afternoon of pain in one wrist, the doctor being called in that evening and finding the wrist slightly swollen and red, and the temperature a bit above normal; one tonsil was reddened, but there was no complaint of sore throat. The following morning he was running about as usual, but in the afternoon there was a return of the symptoms, a little more severe. The following morning he was—apparently—perfectly well, but in the afternoon the symptoms returned in a still more aggravated form. He was put to bed, where he remained several weeks. A few days later the other wrist was involved, while aspirin made no impression. His temperature was higher every day until the eighth day, when it was 104° in the evening.

On the tenth day he coughed and there was found a small area of consolidation in the center of the left lung. For the next few days this consolidation showed increase both upward and downward. After a week this resolved, but the patient was no better and new areas developed.

It was observed that every time a portion of the lung resolved, the joint symptoms were aggravated, so that the wrists, elbows, ankles, and great toe joints suffered in turn, and the case seemed like one of general sepsis. The temperature varied greatly and on a resolution of a part of the lung there would occur an attack of joint swelling with intense erythema, followed by profuse sweating and polyuria. At this time the liver was about three times and the spleen twice the normal size and the urine was loaded with albumin. The leucocyte count was 14,000-19,000.

*Presented at a meeting of the Practitioner's Society April 5, 1912.

A Moro test taken was negative. There was at times absolute flatness of the lungs on percussion, strongly suggesting empyema, but punctures failed to confirm this. The doctor, under the impression that there was general sepsis, punctured the lungs in five different places, with negative results. The aspirated serum and blood were examined for tubercle bacilli, with negative results. The sputum contained capsule cocci and other bacteria but no streptococci or tubercle bacilli. Soon the right lung became involved, and it seemed that not the smallest portion of his lungs escaped consolidation, and some portions were consolidated several times over. The pleuræ were never involved, as the punctures showed a freely movable lung.

After an illness of about ten weeks he was taken to Asheville, N. C., and several physicians pronounced his case tubercular, but they made no tests. He went to Asheville on March 31 and returned on May 6, having lost ground so rapidly during that time that he was brought home to die. He slowly improved after reaching home, and the resolution of small areas of lung on every occasion brought on an attack of joint swelling and symptoms of sepsis.

A favorable circumstance was that the intervals—at first about one week in duration—became longer and longer, and he began to gain in weight. As his lungs improved the superficial lymphatic glands became enormously swollen, as well as those in the axillæ and groins.

The case ran along with very little change until September, when rigidity of spine was noticed, and the upper dorsal and lower cervical verterbræ were thought to be tubercular, and the diagnosis of general tuberculosis seemed unmistakable. The patient was kept flat on his back and when the weather was favorable he was put in a hammock on the porch or was given a ride in a cart built especially for him. Figure 2 is a very good illustration of his appearance at this time, and indeed when he entered the hospital this picture would be faithful to life. The *x*-ray pictures taken on November 22 revealed absolutely nothing in the bony or cartilaginous structures of spine, thorax, feet, or wrists. The lungs and pleura were found almost absolutely normal. The failure of the *x*-ray pictures to throw any light on the subject caused the doctor to abandon the diagnosis of tuberculosis and make one of Still's disease.

I cannot refrain from acknowledging with gratitude my indebtedness to Dr. Kurth for so elaborate a history of the case, and while I have given the above details in abstract I think it only fair to give the following quotation: "In explanation of the case I would state that all the symptoms that go to make up the clinical picture are symptomatic of absorption. There is in the patient some central focus which throws out septic matter into the circulation

at irregular intervals. I believe this focus is somewhere in the chest—probably in the mediastinum."

Shoulders are involved and most of the movements painful. Axillary glands moderately enlarged. Both elbows enlarged over outer side, yet all motions are preserved except pronation to a

Fig. 1.—Case I, before the development of the disease.

slight degree. Wrist joints involved with marked swelling and limited motion which seems quite painful. *X*-ray taken one month ago reported negative. Some days the patient seems lively, moving limbs up and down, but this generally provokes an exacerbation. The upper teeth are bad and peg shaped. The metatarsophalangeal joints are not involved, but the first row of carpals are involved. The hips are held at angle of 90°. Left hip shows no motion; right shows small amount of motion, and with a little coaxing extends to 170°. Knees are involved: right can be extended about 165°; left to about 120°. Some days extension is better. The tibiotarsal and midtarsal joints are involved.

Measurements were taken and are recorded below with some taken April 5. The thorax is well developed; percussion notes are about normal; spinal column seems straight, but presents a little rigidity except in lumbodorsal region, where it seems normally flexible. A few of the cervical glands are slightly enlarged.

April 5, 1912, the following notes were recorded: Since admission there has been a gradual and steady improvement. The treatment adopted was thymus extract beginning on grs. 5, t.i.d. Now getting grs. 5 A. M., grs. 5 M. and grs. 5 P. M. Sleeps well without any aid. Bowels have been regular, while before admission he was obliged to have enema every day or two. At the end of about one month traction was begun in the line of deformity, two pounds to each leg. No local applications to the joints. He has been taken to the roof every day.

At present he can raise himself up in bed and move his head freely. Teeth and gums in good condition; cervical glands slightly enlarged on each side; ribs slightly beaded; apparently no splenic or hepatic enlargement; slight enlargement of glands in left groin.

Puff ball over right shoulder like a small mass of fat, while movements at this joint are restricted to about one-half normal in rotation. Left shoulder joint free from this mass of fat, but more tenderness and more restriction in motion. Right elbow presents slight enlargement of the epitrochlears, some swelling over the head of the radius and a little over the internal condyle, while flexion is perfect and painless as well as extension, and pronation and supination cause a little pain, but are perfect. Same remarks are true of the left elbow, except supination not quite so good and he keeps the forearm preferably in pronation. Wrist joints on both sides are symmetrically puffy on the dorsal aspect, but decidedly smaller than on admission. They present a very good range of motion which is comparatively painless. Metacarpophalangeal joints on each side are not involved, except the thumb joint, which is slightly involved. The proximal row of phalangeal joints shows a little swelling, but function is very good. Nothing at the distal joints.

Right hip can be extended to about 170° and flexed past 90°; abduction limited to a small arc; adduction perfect. These movements are better actively made than passively. Left hip held in moderate abduction; extension limited to about an angle of 135°; adduction limited to a small arc; abduction better; flexion limited to about 110°; much more sensitive than right hip. In fact the whole left side is more sensitive than the right side. He can extend right knee to about 170° and flex past 90°; can extend left knee only to 135° but can flex to an acute angle. These joints are not very

Fig. 2.—Case I, showing the disease at its height.

sensitive on handling. Right foot hangs preferably in equinus but dorsoflexion can be made to about 90°; left foot in moderate valgus and has a fair range of motion at tibiotarsal joint. No involvement of the metacarpocarpal joints and none of the toe joints.

Comparative measurements:

January 19, 1912.	April 5, 1912.
Right wrist—5½.	Right Wrist—5.
Left—5¼.	Left—5¼.
Right Knee—7½ by 8¼ by 6.	Right Knee—6¾ by 7½ by 6.
Left—7½ by 8¾ by 6.	Left—7¼ by 8 by 7½.

Left—6 by 7¾ by 7¼.	Left—5½ by 7¼ by 6½.

Dr. F. M. Jeffries, pathologist to the hospital, reports as follows: March 27, 1912, 11 A. M.—Red count, 5,000,000; white count, 8,000; hemoglobin, 85 per cent.; polynuclears, 60.8 per cent.; lymphocytes, 37.7 per cent.; eosinophiles, 0.6 per cent.; transitionals, 1 per cent.; nucleated reds, none.

The *x*-rays taken shortly after admission and again within the past few days are absolutely negative and are here presented for inspection. Dr. Darling, the hospital radiographer, confirms our own observations. The boy's appetite has been good, he sleeps well, and the further treatment will include fixation of the limbs in correct position rather than traction, as this cannot be made efficiently because of the number of joints involved in the deformity. Furthermore, in the absence of any suggestion of an osteoarthritis, immobilization offers the best means of securing recession of the periarticular infiltration.

A note under date of June 28 is as follows: Lungs perfectly clear; no deposit of any kind. Lower limbs straight and free from deformity though requiring a pad over the knee and a foot plate to keep them so. In a plaster-of-Paris bed which was made for him several weeks ago, just after the case was presented, and applied under ether, the deformity fully corrected, he has been very comfortable, easily handled. The swelling about the hips, knees and ankles has undergone a certain amount of resolution.

On June 30 the patient was discharged from hospital, a plaster-of-Paris bed having been changed for a kind of wire cuirass, devised by Dr. Kurth. In this he is very comfortable; the limbs are held straight. The extract of thymus is to be continued. Later he will be put on his feet, and it is believed that a good result will follow and a fair range of motion will be secured.

We had in the Hospital for Ruptured and Crippled several years ago a typical case which ran through the different stages and finally yielded to an attack of measles. I think this case was shown both by Dr. Whitman and myself at different times at meetings of the Orthopedic Section of the academy. It is interesting to note that three of Still's cases improved immediately after the onset of other infections, namely, measles, scarlatina, and catarrhal jaundice, as did the case just referred to.

Another case was treated in the Out-Patient Service of the Hospital, the notes of which have been furnished by Dr. W. W. Strang of this city: March 1, 1907, male, aged five years, was brought to the Out-Patient Department of the Ruptured and Crippled Hospital. The patient was well until one and a half years of age when he had measles; recovered without complication. Two months later had high fever lasting two or three days. The physician then called said the child had "cold in his joints."

At three years of age the joints generally were enlarged and the child stopped walking. The child was pale; mucous membranes very pale; forehead somewhat prominent; teeth fairly good; joints generally enlarged; swelling consists of thickening of soft parts overlying joints; no tenderness and very little pain on movement of joints; motion limited in all joints; fingers fusiform; cervical lymphatic glands indurated and freely movable; axillary glands markedly enlarged, separate, firm, and freely movable; moderate rachitic rosary; heart and lungs normal; abdomen protuberant; umbilical hernia; spleen enlarged and firm, extending one and a quarter inches below free border of ribs; liver enlarged, extending two inches below ribs; abdomen otherwise negative; urine and blood negative. (See Fig. 3, from a photograph.)

Upon successive visits the child was found to have a temperature at 2 P. M. ranging from 99° to 101.8°. After various kinds of medication without much effect, on April 12, 1907, thymus gland (B & W) Grs. 1½ t. i. d. was ordered.

Fig. 3.—Hospital Case 11.

April 24, 1907, patient seemed much improved, appetite was better and sleeping improved. No fever had been noticed by the parents, though temperature 99.5° to 100° was found on examination.

On May 3 the patient was walking alone; joint movements much increased; lymphatic glands markedly smaller.

On May 24, the report was: Excellent color; stands straight; temperature 99°; liver and spleen slightly smaller. Thymus gland increased to Grs. 5 t. i. d.

September 20, 1907: Patient runs about but tires easily.

April 3, 1908: Pulse 78; temperature 98.8°; walks alone for two or three blocks; joints about the same; heart slightly irregular, so medicine is stopped for two weeks.

November 20, 1908: Thymus was stopped for a

while during the summer, followed by weakness, fever, and pallor. For past two months has been taking Grs. 5 t. i. d. Color fair; walks well and stands straighter; pulse 99; temperature 99.5°; eats and sleeps well, never complains.

After this time the patient ceased coming to the hospital and a letter sent to his address was not answered.

Dr. P. W. Nathan was on the Out-Patient staff at that time and it was on his suggestion that the thymus extract was employed. In an article published in the *American Journal of the Medical Sciences* for June, 1909, on "The Nature, Diagnosis, and Treatment of Metabolic Osteoarthritis" he has an illustration of this case as "So-called Still's Disease."

I beg to append to these reports an abstract of a paper by Dr. George F. Still, published November 10, 1896, in the transactions of the Royal Medical Chirurgical Society of London. The polyarthritis occurring in children which he describes he says differs in its clinical aspect and morbid anatomy from rheumatoid arthritis of adults, suggesting distinct pathology.

The paper was based on twenty-two cases—nearly all in the Hospital for Sick Children, Grand Ormond Street, London. "The disease may be defined as a chronic progressive enlargement of joints, associated with general enlargement of glands and enlargement of spleen." The onset is almost always before second dentition. Ten out of twelve cases began before six years; the earliest at fifteen months. The onset is usually insidious. Stiffness in certain joints occurs and they slowly become enlarged. Occasionally the onset is acute with pyrexia.

Enlargement of joints feels and looks more like general thickening of tissues around joint than bony enlargement. Absence of osteophytic growth and of anything like bony lipping even after years have elapsed is striking. No redness or tenderness of joints except in very acute cases. Absence of pain striking but may be present in slight degree. Limitation of motion, chiefly extension, is always present. Joints earliest affected are usually the knees, wrists, and those of cervical spine. Subsequent order of affection being ankles, elbows, and fingers. Affection is symmetrical. No tendency to suppuration nor bony ankylosis.

"Perhaps the most distinctive feature is the affection of lymphatic glands, the enlargement being general, which subsides as disease subsides and increases if joints become worse." Glands most affected are the supratrochlear, those along brachial artery, those in axilla, those in Scarpa's triangle, those deep in illiac fossa along the iliac artery, and in the posterior triangle of neck. Enlargement of the spleen is also a striking feature. Definite in nine of twelve cases.

Heart shows no evidence of valvular disease. Anemia generally present. Sweating often profuse and not related to temperature. Temperature usually characteristic, appearing in periods, lasting only a few days, of pyerxia.

A remarkable feature is the general arrest of development when the disease begins before second dentition. Mental development not affected. Disease not fatal. Still could find no definite cause. Dirt and unsanitary surroundings played no part in etiology. Three of his cases improved after other infections. One after measles, one after scarlatina, and one after catarrhal jaundice.

Three post mortems showed marked thickening of joint capsules and connective tissue adjoining, and thickening and vascularization of synovial membrane. Cartilage may be normal; sometimes slightly pitted.

Points of difference between this and rheumatic arthritis of adults are: Absence of cartilaginous change; thickening of capsule and fibrous tissue; enlargement of spleen; occurrence of adherent pericardium.

Still concluded there were no bony changes, but he was not present at the three post-mortems made.

16 Park Avenue.

THE DE KEATING-HART METHOD OF THERMO-RADIOTHERAPY.*

By WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D.,

NEW YORK.

In a former paper on Fulguration (Medical Record, July 6, 1912) reference was made to cases in which fulguration alone was not indicated, and in which a combination of fulguration with "thermo-radiotherapy" has been employed to seeming advantage by de Keating-Hart. The method consists briefly, in the sensitization of the tissues by fulguration, or other means, and their irradiation by means of *x*-rays, the skin surface through which the *x*-rays must pass being previously or simultaneously cooled in order to prevent *x*-ray dermatitis.

The procedure and the theory upon which it is based was given to the profession for the first time during the demonstrations at the New York Skin and Cancer Hospital in December. It is now being published for the first time. The method is too new to permit a definite statement with reference to its effects, or to predict its future. According to its originator, some very astonishing and quite unhoped-for results can be reported, a few examples of which are herewith presented.

A number of cases were treated by this method under de Keating-Hart's direction, during his recent visit, and the treatment has been continued in these and other cases since that time.

The following cases are fair examples of the results obtainable with this method. The histories and photographs were furnished us by de Keating-Hart.

Case I.—This is intended to show the inhibitive action which cold exerts against the effects of the rays. A man who was suffering from an epithelioma of the face extending to the cranium and to the brain had been subjected to the *x*-rays, and a few days after the application he had suffered from a radiodermatitis, despite the care taken by the specialist to avoid such an accident. The patient, refusing to submit to further applications of radiotherapy, presented himself to de Keating-Hart. Upon the promise of the latter not to burn him the patient agreed to allow a treatment. The *x*-ray was applied to the skin every eight days for several weeks, during which time the skin showed no untoward symptoms. Before each treatment the skin surface to be traversed by the *x*-rays was chilled, either by means of bellows, evaporating a little water imbibed in a piece of gauze placed upon the region, or by means of a small sack of crushed ice. It is added that the patient had a very much congested and warm face, which explained his susceptibility to the *x*-rays.

The other cases have reference to particularly rapid results with the *x*-rays upon cancers previously warmed.

Case II.—This case was that of a woman afflicted with

*Read in part before the New England Association of Physical Therapeutics, Boston, April 12, 1912. Illustrated with lantern slides. Delivered in part, with the presentation of patients, at the Eighth Annual Clinical Lecture on Cancer, New York Skin and Cancer Hospital, April 24, 1912.

an inoperable cancer of the uterus which had fixed this organ in the pelvis and formed a large glandular metastasis in the left groin. The compression caused by these glands had produced considerable edema of the left leg and foot. The patient suffered horribly despite the six or seven

Fig. 47.

daily injections of morphine. Thermo-radiotherapy was applied in two sittings within four days. At the first sitting it was applied by means of a thermopenetrative electrode introduced into the vagina, the other pole being placed upon the left lateral wall of the abdomen a little below the spleen. At the second sitting the temperature of the pelvic region was increased by means of a hot vaginal douche with water at 50 degrees centigrade for twenty minutes. Both calorifications were accompanied by radiotherapy through the chilled skin of the abdomen. (As usual, the dosage given was 4H. ten Benoist.) The result was very remarkable and rapid. From the first application the pains diminished, and after the second they disappeared. The swelling of the leg subsided so that morphine was no longer necessary. The internal tumor diminished by one-half in eight days and the inguinal glands had grown smaller. At the same time some very remarkable cytolytic phenomena of intoxication appeared, viz., profuse diuresis (4 to 5 liters in twenty-four hours), fever from 39° to 40.5° C., and during the eight days symptoms of depression alternating with nervous excitability, etc. Then everything went well again, and several weeks later, without other treatment, the pain had not reappeared, and the local condition remained about the same. This patient is still under treatment.

Case III.—The third case is somewhat similar to the preceding. This was an extensive cancer of the vagina fixed to the rectum and involving the adjacent structures. The uterus was apparently invaded. The surgeon, Dr. Rouland, who referred her to de Keating-Hart, considered the case inoperable, or at least that no good results could be expected from operation. Three applications of thermo-radiotherapy were made, extending over three weeks. This sufficed to reduce the tumor to the size of a peach stone—a small indurated mass situated upon the posterior vaginal wall, completely free from the rectum. In this case very warm water was used to heat the parts and radiotherapy in the dosage of 4 H applied through the pelvic route.

Case IV.—This case is that of a woman (Figs. 47 and 48) afflicted with chondrosarcoma which had recurred twice in the palm of the hand. The lesion was deep and the flexor tendon was invaded, as shown in the photograph. The surgeons who had seen the case proposed amputation of the forearm, but the patient refused, presenting herself to Dr. de Keating-Hart for treatment. He began by extirpating the greater part of the tumor with a knife, then fulgurating this area. Deep down, however, there remained some masses in contact with the bones and tendons. Some days later he plunged a high-frequency needle into these masses and simultaneously allowed the *x*-rays to play upon them. In a few sittings the induration had dis-

Fig. 48.

appeared and four weeks later the hand was healed, as shown in the second photograph. The function of the hand is almost normal, and the pains, which had kept the patient awake, disappeared after the first exposure.

Theory.—Again we quote directly from the communication of de Keating-Hart:

"Every luminous radiation passing through a living organism, determines in it biochemical reactions, the intensity of which varies with the quantity and duration of the exposure from a mere over-excitement of normal transformation to the destruction of cell-life. Such is the law regulating the relations of living beings to light, whatever the length of the luminous vibrations.

"It must not be overlooked, however, that a knowledge of the quality, number and duration of irradiations does not necessarily imply a knowledge of the length and intensity of biochemical reactions.

"The explanation of the unequal effects produced by radiations of the same strength must be sought in the morphological differences and the biological state of the cells themselves at the moment.

"Every radiotherapeutist, however expert he may be, and even with the use of the same instrumentation under the same general conditions, sees very different results according to the individual. It is well known that certain pathological tissues are much more sensitive than others to Röntgen rays.

"In 1907, Bergonie and Tribondeau (of Bordeaux) threw some light on these hitherto empiric notions. Their researches were made to determine the amount of cell destruction in the organic depths with radiations which were innocuous to surrounding or more superficial tissues. From their work these authors have arrived at certain conclusions which, if not sufficient to explain all the known facts, permit one to understand at least many important phenomena.

"The following three laws are worth remembering: The activity of rays is proportional: *First,* to the reproductive activity of the cells; *second,* to the duration and constancy of their karyokinetic movements; *third,* to the higher differentiation of cell morphology and function.

"From these data we may readily conclude that the effect of *x*-rays on pathological cells is not specific. It is thus easily understood how neoplasms are destroyed by *x*-rays that pass through the more fixed normal cells. For the same reason certain tumors of rapid growth are more radiosensitive than tumors characterized by less constant and intensive karyokinesis.

"Of a similar nature are the conclusions drawn by Dominici and Cheron from radium effects. These experimenters not only observed a greater radium-fragility in the case of epitheliomata than in that of sarcomata, but they noted also the same difference between embryonic sarcomata and fibrochondrosarcomata, the cells and functions of which are more specially differentiated.

"In the same way also Schwartze observed that moistened and sprouting seeds are more radiosensitive than those which are previously dried. In this we have an obvious confirmation of Bergonie's findings.

"On the other hand, these laws do not by themselves explain the great skin-sensitiveness from which certain patients suffer during every exposure to *x*-rays, no matter how short the sitting may be.

"Furthermore, these laws do not explain the resistance offered to the Röntgen rays by certain tumors which were in the very beginning of treatment markedly radiosensitive. This is still more remarkable when we remember that cutaneous tissue becomes weaker at every successive radiotherapeutic sitting.

"Another contradictory fact was observed by Gerhartz: that the genital organs of frogs (organs, however, made up of karyokinetic cells) were not found to be sensitive to the *x*-rays. This would appear to be contrary to Bergonie's rule and to the conclusion drawn from Schwartze's experiments on seeds.

"Paul Becquerel, upon exposing dried spores of

Fig. 49.

Fig. 50.

Case V.—The fifth case (Figs. 49 and 50) is that of a man who was suffering from Hodgkin's disease, with generalized lymphosarcoma and leukemia. He showed numerous large tumors, the most important of which were situated in the cervical, axillary, and inguinal regions, tumors of rapid growth developing almost simultaneously everywhere. The spleen, while not enormous, was perceptibly increased in size. For three years this patient had undergone various kinds of treatment, among which were *x*-rays and two surgical operations. Electric treatment gave him marked relief at first, a number of the neoplasms rapidly softening under the action of radiotherapy. Then, as often happens, the tumors, instead of continuing to disappear, seemed to receive a new stimulus to growth, so that the specialist in charge finally advised cessation of the treatment. When the tumors had acquired an enormous size the patient was admitted, in June, 1911, to the service of Prof. Delbet, at the Neckar Hospital. Prof. Delbet operated upon two large masses situated in the neck and in the groin. The patient, terrified by these repeated operations, left the hospital and entered Dr. de Keating-Hart's Hospital.

The areas operated upon already showed new recurrences, and the non-operated tumors, shown in the first picture, grew very rapidly. They were of a hard, nodular consistency, and a histological examination at the Neckar Hospital confirmed their malignant nature.

The patient was treated every day, or every other day, for three weeks by injecting into one of the tumors artificial normal serum at a temperature of about 50 degrees C., nearly equal in quantity to the size of the tumor before the injection. Immediately after each injection an *x*-ray treatment (4 H, 10 Benoist) was given. One sitting for the small tumors and two for the large ones was sufficient to soften them in a few days.

This patient, who had been condemned to a very rapid death eight months previously, is in an almost florid state of health, and has taken up his work again. There are still a few disseminated tumors not yet softened, but the great majority and the largest of them have disappeared as one may see from the last picture.

yeast, found that these spores are very quickly sterilized at normal temperature and but very slowly when frozen.

"When we consider that the experiments of Gerhartz were made during the winter on frogs, animals whose temperature is variable, we can only conclude that, as in Becquerel's experiments, cold seems to be opposed to the destructive action of rays on living cells.

"Histopathology, clinical researches, and personal experience have confirmed the statement that I made at the Dijon Congress, namely, *other conditions being equal, the radiosensitiveness of tissues depends upon their temperature.* In other words, the higher the temperature of tissues (between the normal vital limits) the greater the destructive power of radiation upon them. An excellent illustration of this is shown in the picture (Fig. 51).

"The patient, being treated for cancer of the right breast, presents needle marks upon the left breast. The needles were plunged into the skin and served with thermopenetration. During respiration the needles were thrown out upon the skin two or three

Fig. 51.

times without any apparent mark. X-rays, applied immediately after, revealed these various displacements through the radiodermatitis produced in the burned areas."

All these clinical and experimental facts, however interesting they may be, must be confirmed by therapeutics. The researches of de Keating-Hart on the radiosensitiveness of cells were made with therapeusis in view. Röntgen-therapy, in his opinion, would be the best kind of treatment for cancer if it would sufficiently work on deep tissues without destroying the healthy overlying tissues. If it is possible to render abnormal cells radiofragile and healthy organs radioresistant, the best possible results can be obtained. Such are the principles of his method of thermo-radiotherapy, which consists in *cooling the skin and heating the diseased tissues during or before the application of x-rays.*

Technique—Thermo-radiotherapy is applied in three different ways, as follows:

(1) In the case of tumors with abundant blood supply, such as sarcomata, physiological hot serum is injected at 50° C., and in such a quantity as to raise the internal temperature of the neoplasm to about 41° or 42° C.

(2) In case of cancers developed in the natural cavities (rectum, vagina, stomach), irrigations as warm as possible are used during a time varying with the needs of the individual case.

(3) In tumors of woody consistency, that can be heated neither by injection nor irrigation, high-frequency currents are employed either by passing the current through needles thrust into the skin, or through an electrode placed on the skin surface.

The last-named method of applying currents is not new. It has been employed by several persons, but with serious inconvenience because, by rendering the skin more radiosensitive than the deep-seated tumors, they have produced radiodermatitis, making the subsequent application of the current impossible.

A natural consequence of the law controlling the relation of temperature to radiosensitiveness led de Keating-Hart to obviate the difficulty just mentioned by *cooling* the organs which he would protect. This is accomplished by several means, two of which may be mentioned.

First, the surface to be protected by cooling is covered with cracked ice wrapped in cotton.

Second, a special apparatus may be employed which cools by blowing the dampened surface with a bellows.

Whenever possible, *x*-rays should be applied during the heating of the cancer, especially when the neoplasm is small and superficial. If the mass is deeply situated, as in uterine cancer, it may retain its warmth long enough for the irradiation to follow immediately after the warming process.

The irradiation must be subjected to the usual rules of radiotherapy. The longer and more frequent the exposure, without destroying the normal surrounding tissues, the more rapid are the local results. The results may sometimes be too rapid, which fact calls for great care, inasmuch as the cytolysis of the tumor may be the cause of serious autointoxication. This is particularly true of epithelial tumors.

Conclusions.—From a study of the data cited, and from the experience described, de Keating-Hart arrived at the following conclusions with reference to thermo-radiotherapy:

(1) That the *x*-rays have a more intense action upon warmed cells than upon cold cells.

(2) That the application of this principle under the name of thermo-radiotherapy in the treatment of cancer, by previously cooling the surface of the normal tissues to be traversed by the *x*-rays, produces more rapid destruction of the cancerous tissue with a weaker dose.

(3) That this treatment is applicable to the majority of cancers, but the autointoxication brought about by the cytolysis renders it advantageous to remove as much as possible of the cancer and to fulgurate the field of operation in operable cases.

(4) That in inoperable cases, and with patients who refuse all operative interference, thermo-radiotherapy alone may be employed, care being taken to prevent too rapid cytolysis and consequent autointoxication.

(5) That cases in which the cancer has been completely removed and fulgurated show the same sensitiveness to *x*-rays as do warmed cancers.

Thermo-radiotherapy, alone or in conjunction with fulguration, according to the requirements of the individual case, is being tested at the New York Skin and Cancer Hospital. We are not ready

yet to even express an opinion concerning its merits, further than to say that we would not be testing it if it did not hold out a modicum of hope of at least ameliorating suffering.

In due time the cases treated by means of thermo-radiotherapy, along with those treated by fulguration, will be reported in detail.

34 Gramercy Park.

A REPORT OF TWELVE CASES OF MENTAL DISEASE TREATED WITH SALVARSAN, WITH SPECIAL REFERENCE TO BLOOD-PRESSURE DURING INJECTION.*

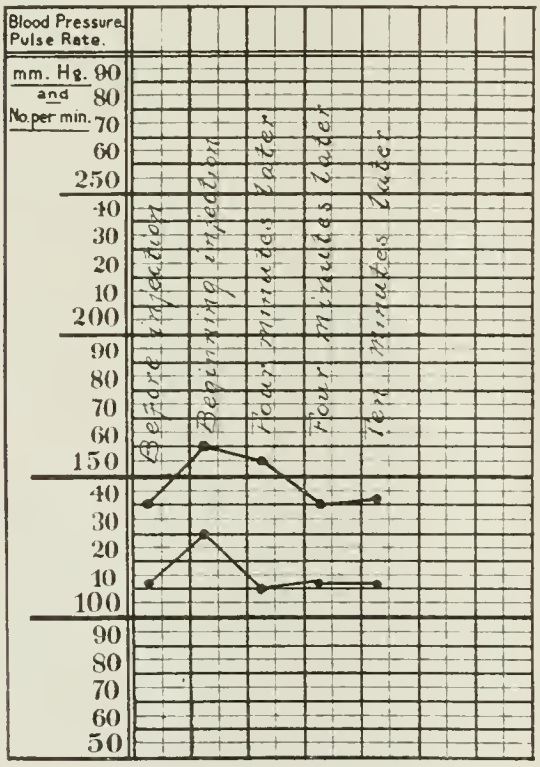
By CLYDE R. McKINNISS, M.D.,

NORRISTOWN, PA

FIRST ASSISTANT PHYSICIAN, DEPARTMENT FOR MEN, STATE HOSPITAL FOR THE INSANE.

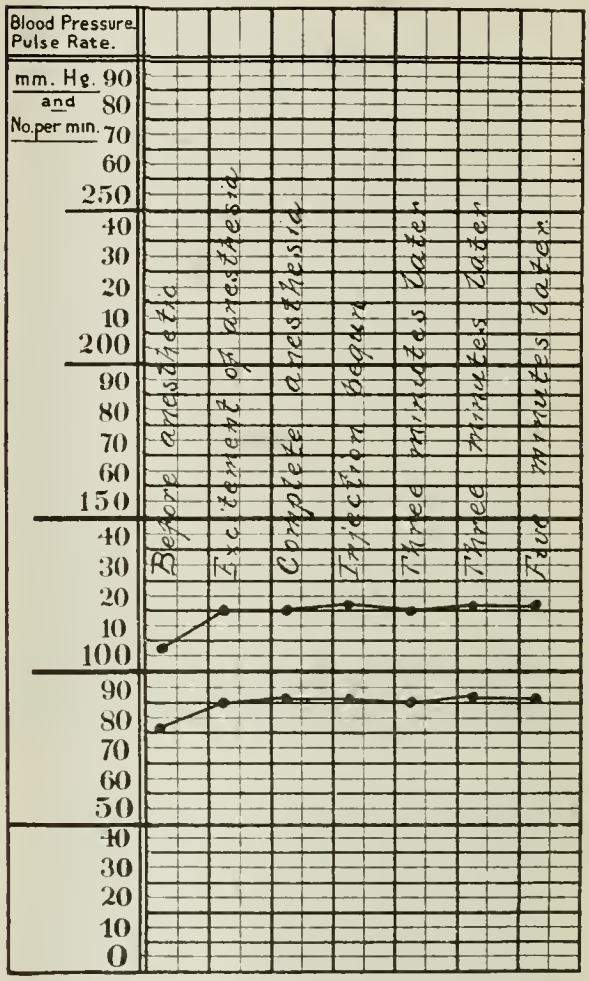
It has been almost two years since Ehrlich introduced salvarsan as an antisyphilitic remedy and the immense literature which has appeared since its introduction shows with what enthusiasm we have received it. For a time Ehrlich attempted to direct its use by placing it in the hands of a limited number and later by circular letters advising as to the dosage and method of administration. Some unfavorable results have been reported, not all of which can be charged to the drug itself, and while at present its use may be more restricted than was at first anticipated, it has undoubtedly gained a permanent place in the treatment of syphilis.

Our first use of salvarsan was in March, 1911, a few months after Ehrlich had recommended the intravenous method of administration in preference to the subcutaneous or deep injections, and all



Case I.—No anesthesia; dose, 0.3 gm. in 100 c.c. salt solution; upper line systolic, lower diastolic pressure.

our patients have been injected in the superficial veins of the arms, the median cephalic or basilic being used. In preparing the drug for injection we have followed, in a general way, the method described by Schreiber, which is as follows: "Into a graduate holding 250 c.c. drop 10 to 20 c.c. of



Case III.—Ether anesthesia; dose, 0.4 gm. in 185 cc. salt solution; upper line systolic, lower diastolic pressure.

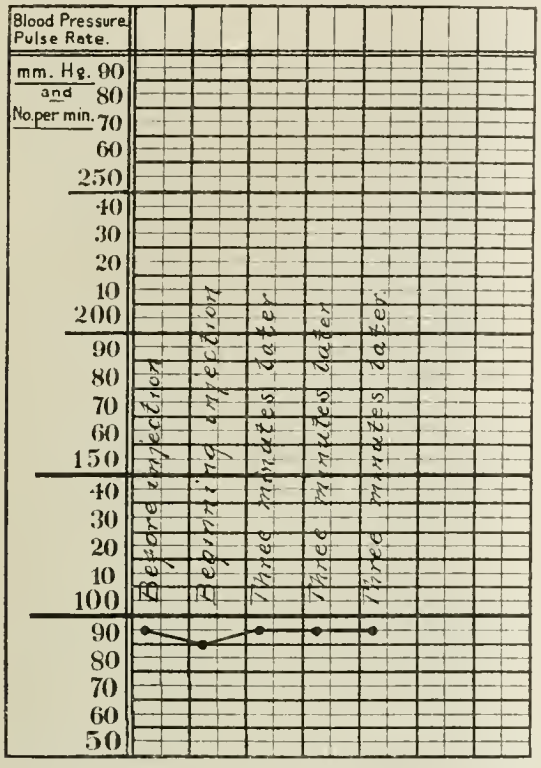
sterilized water, add the required dose of 606, and mix thoroughly until there is a clear solution; add sterile water, or better normal salt solution, to the 100 c.c. mark, then add for 0.1 of 606, 0.7 of normal sodium hydroxide solution and mix until the precipitate is thoroughly redissolved. If after thorough mixture the solution is not clear add a few more drops of the sodium hydroxide solution to produce this and then add sufficient normal salt solution to make 200 to 250 c.c."

We have changed the strength of the sodium hydroxide solution, using at one time a 20 per cent. and again a 10 per cent. solution (normal sodium hydroxide solution being a 4 per cent. solution of sodium hydroxide in water), which by means of a pipet, was added drop by drop to the solution of salvarsan, thus guarding against an excess of the alkali. The total amount of normal salt solution injected has varied from 95 c.c. to 195 c.c.

An examination of the eye grounds, heart, and kidneys was made in each case before treatment, and during the injection records of the blood pressure were made at intervals. The patients were prepared as for surgical operation and the injections were made under conditions as nearly aseptic as possible. A gravity pressure apparatus was used (Daland) and the solution was kept at as near the body temperature as possible.

*Read before the Philadelphia Psychiatric Society March 8, 1912.

We have treated twelve patients and given fifteen injections of salvarsan, and in every case mercury, either by mouth or inunction, has been used as an adjuvant. In only three cases was it



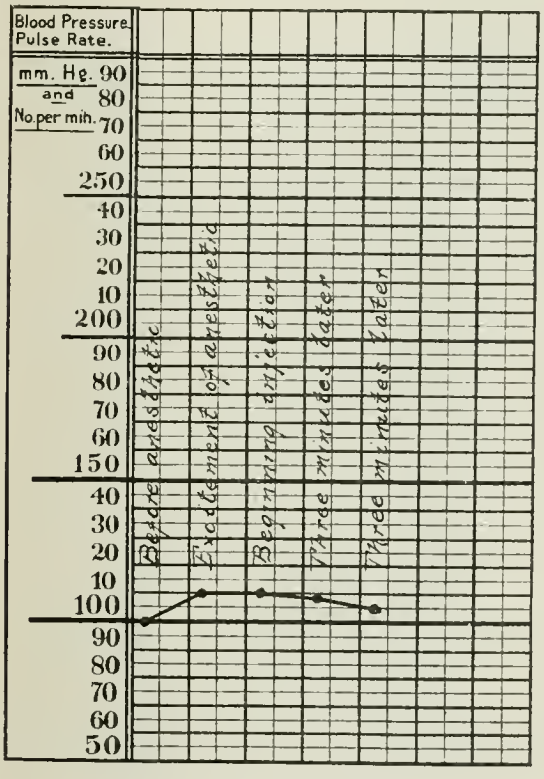
Case IV.—No anesthesia: Dose, 0.4 gm. in 130 c.c. salt solution; systolic pressure.

necessary to cut down on the vein to insert the needle and only two required a general anesthetic. All the patients were kept in bed for two to six days after injection.

Case I.—L. F. H., male, white, aged 44 years; moderate alcoholic; married; no children. Contracted syphilis at 32 years of age. Admitted to Norristown State Hospital April 20, 1909. Psychosis of three weeks' duration, having commenced as a depressed state and passing into a state of excitement with marked psychomotor activity and vivid aural and visual hallucinations. Urine contained hyaline and granular casts; superficial lymph glands enlarged; knee jerks reduced; Rhomberg sign present; hearing slightly impaired. Examination of eye grounds showed no abnormalities; pupils dilated, unequal in size, and reacted sluggishly to light. Diagnosis: Paresis (circular form).

At intervals since he contracted syphilis he had some treatment and after he came to the hospital he was given mixed treatment (corrosive sublimate 1/32 gr., and potassium iodide 10 gr., t.i.d.) for one month, and then inunctions of mercury for six weeks. Examination of the spinal fluid at this time (June 30, 1909) showed it to be clear, colorless, and of normal tension; Noguchi butyric acid reaction negative; cell count 50 lymphocytes per cm. His condition improved so much that he was allowed to go home on a visit after four months in the hospital but was returned after nine months in a state of mild depression. He was given a six weeks' course of mercurial inunctions with little effect. On January 31, 1911, a Wassermann reaction on the blood was $++++$ and the spinal fluid showed slightly increased tension, colorless; Noguchi reaction doubtfully positive; Wassermann $++++$; cell count 17 lymphocytes per c.m. On March 7, 1911, he was given 0.3 gm. salvarsan in the left median cephalic vein, no anesthetic being used. The needle was readily inserted into the vein after a tourniquet about the arm had caused some distention; the amount of normal salt solution injected was 100 c.c., and the rate of flow was 20 c.c. per minute. Instead of a rise in blood pressure there was a gradual fall, as shown by the chart. Slight flushing of the face was present during the injection but no discomfort. About two hours later he had a moderately severe chill and a temperature of 101°.

Before the injection he had been dull and took little interest in his surroundings, but that evening he was talkative and somewhat expansive in his ideas. Seven days after the injection he wrote a well-composed letter to his wife requesting his removal from the hospital, though he had not written any for many weeks before. Within three weeks he was quite grandiose, talkative, and excited; filthy in his habits. An examination of the spinal fluid six weeks after the injection (April 18, 1911) showed it to be clear, colorless; Noguchi reaction positive; Wassermann $++++$; cell count 16 lymphocytes per c.m. He was then given 0.6 gm. salvarsan (preceded by a spinal puncture) in the left median cephalic vein; no anesthetic, no difficulty in inserting the needle; amount of salt solution used 195 c.c.; rate of flow 20 c.c. per minute. Patient experienced no discomfort until two hours afterward, when he had a severe chill with rise of temperature. He gradually became dull and filthy; took no interest in relatives or friends, but after two weeks he passed into a state



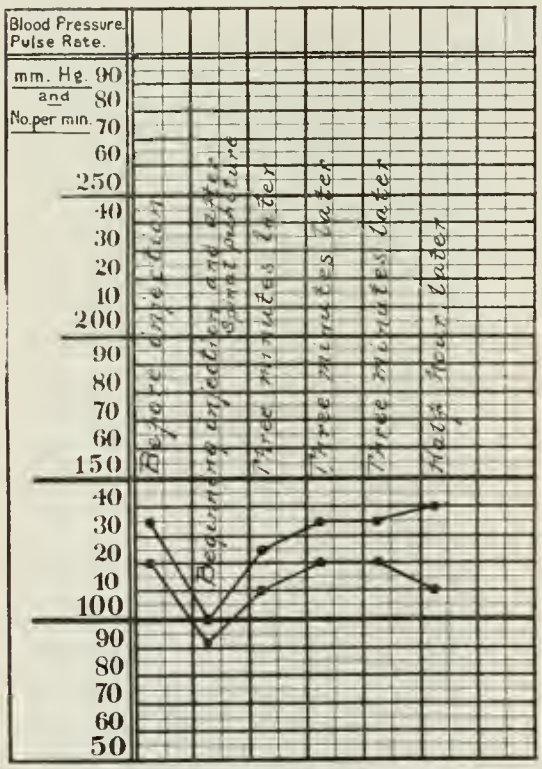
Case V.—Ether anesthesia: Dose, 0.4 gm. in 125 c.c. salt solution; systolic pressure.

of noisy excitement with vivid hallucinations and died from exhaustion two months after the last injection.

Case II.—M. J. G., male, white, aged 45 years;

married (wife insane); no children. Moderate alcoholic. Onset of psychosis two years before admission to the hospital (October 12, 1908). Was depressed, weeping, retarded, and self-accusatory. Syphilis was denied, but he had contracted gonorrhea several years before admission. Knee jerks were reduced; pupils unequal, irregular in outline, and reacted sluggishly to light. Tongue, facial muscles, and fingers showed a fine tremor. Eye grounds normal. Diagnosis: Paresis (depressed form).

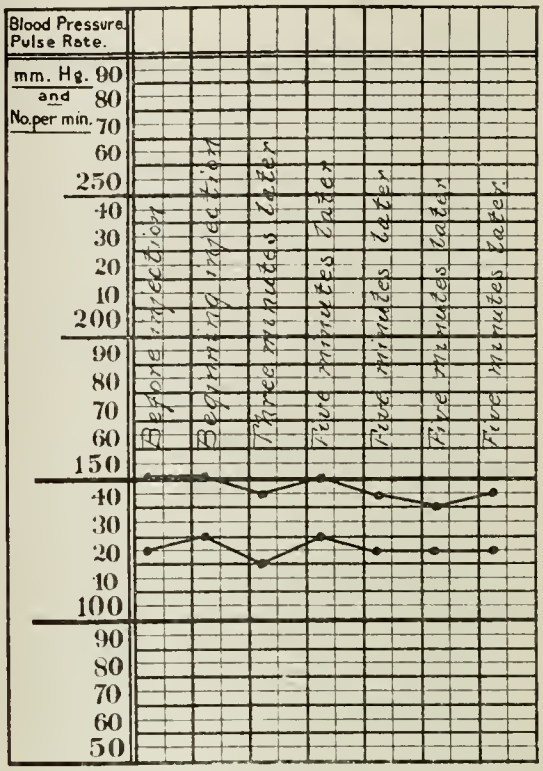
He was given mixed treatment for two months and a Wassermann reaction (December 11, 1910) was $++++$; spinal fluid was of high tension; Noguchi strongly positive; Wassermann $++++$; cell count 4 lymphocytes per c.m. He was then given 0.3 gm. of salvarsan in the left median cephalic vein (preceded by a spinal puncture), the vein being quite small it was necessary to cut down on it under cocaine anesthesia, to insert the needle. One hundred c.c. of salt solution was injected; rate of flow, 20 c.c. per minute. No unpleasant symptoms appeared. Patient improved some in that he was less retarded; took an interest in his environment, worked some about the ward, and attended the entertainments. On April 18, 1911, examination of spinal fluid showed it clear, colorless; Noguchi positive; Wassermann $++++$; cell count 31 lymphocytes per c.m. He was then given (April 18, 1911) 0.6 gm. salvarsan in the right median cephalic vein (preceded by a spinal puncture), 140 c.c. of salt solution being injected; rate of flow, 20 c.c. per minute. Eight hours after the injection he had a slight rise of temperature. Very little improvement followed; he is still in the hospital, though he has been allowed



Case VI.—No anesthesia: Dose, 0.3 gm. in 95 c.c. salt solution; upper line systolic, lower diastolic pressure.

to go on a visit for a day at a time. Talks little, except of his own unworthiness. A Wassermann reaction on the blood (February 21, 1912) was $++$.

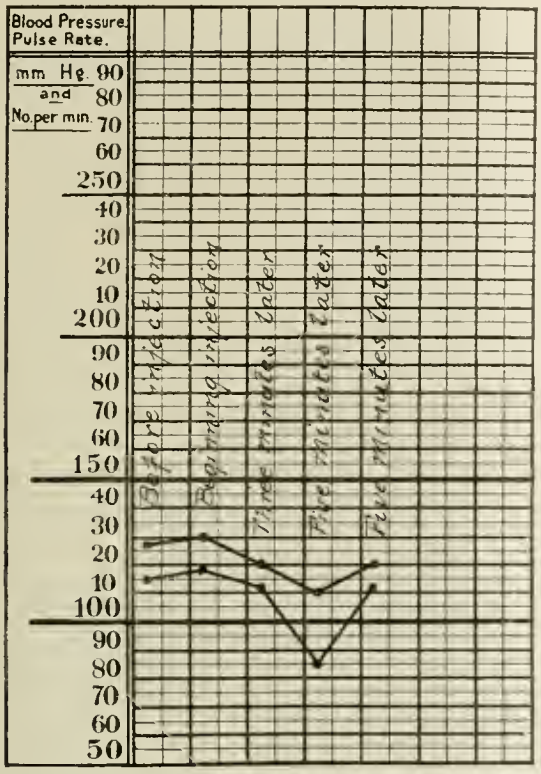
Case III.—R. V. H., male, white, aged 47 years; married; moderate alcoholic. Contracted syphilis at 22 years of age and received some treatment at the time. Admitted to the Norristown State Hos-



Case IX.—No anesthetic: Dose, 0.6 gm. in 140 c.c. salt solution; upper line systolic, lower diastolic pressure.

pital October 24, 1910. Onset of psychosis six months prior to admission, though eight years before he had a period of a few weeks following the death of a child, when he was irritable, talkative, and excitable. The present attack begun with a rather sudden change to mild elation, pressure of activity, and sleeplessness, which led to his commitment to the hospital. When admitted he showed psychomotor restlessness; talked almost continually, and at times a tendency to a flight of ideas was observed. He expressed rapidly changing delusions of persecution and grandeur, weeping and laughing. Pupils were equal and regular in outline but reacted sluggishly and with limited range to light. Knee jerks exaggerated; speech somewhat slurring. A tentative diagnosis of paresis was made, though in many ways he suggested the manic phase of manic-depressive psychosis. He was given mixed treatment and inunctions of mercury for four months and two examinations of the blood showed Wassermann $+++$; spinal fluid was clear, colorless, of low tension; Noguchi reaction positive; Wassermann negative; cell count 25 lymphocytes per c.m. He was then anesthetized and given 0.4 gm. salvarsan in the left median cephalic vein, 185 c.c. salt solution being injected; rate of flow, 10 c.c. per minute. As seen by the chart the blood pressure rose during the excitement of etherization and again with the beginning of the injection of salvarsan. No unpleasant symptoms followed until the eleventh day, when he had two general convulsions which were apparently in no way the result of the salvarsan. No improvement was seen and he died two months after the injection from exhaustion of paresis. The findings at autopsy were those of paresis.

Case IV.—A. T., male, white, aged 48 years; married, one healthy child. Contracted syphilis at 22 years of age, for which he received six months' treatment. Moderate alcoholic. Admitted to the



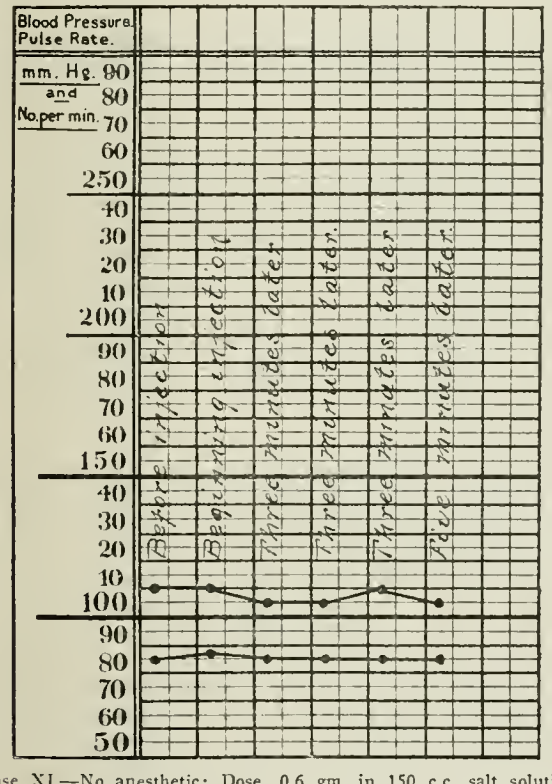
Case X.—No anesthetic: Dose, 0.6 gm. in 150 c.c. salt solution; upper line systolic, lower diastolic pressure.

Norristown State Hospital June 13, 1907, with the onset of mental symptoms one year before that time, though for nine years he had had tabetic symptoms of tingling and pricking of the feet, gastric crises, and girdle pains. When admitted he was quite grandiose and noisy, filthy in his habits, profane and obscene in language. He had moderate arteriosclerosis, gait unsteady, and Rhomberg sign marked; knee jerks abolished, Argyl-Robertson pupils, fine tremor of tongue and facial muscles, an occasional involuntary jerking of the leg muscles. Examination of eye grounds, after pupils were dilated, was negative. Diagnosis: Taboparesis.

A Wassermann reaction on the blood (December 7, 1910) was ++, and spinal fluid (March 14, 1911) showed normal tension, slightly blood tinged: Noguchi reaction weakly positive; Wassermann negative; cell count showed no lymphocytes. He was given 0.4 gm. salvarsan in the left median cephalic vein (preceded by a spinal puncture), no anesthetic, injection was easily made; 130 c.c. of salt solution was injected; rate of flow, 20 c.c. per minute. No unpleasant symptoms resulted; blood pressure showed little change. About a half hour after the injection he complained of slight headache and nine hours later temperature rose to 101.4°, but returned to normal the following day. A Wassermann reaction on the blood (April 17, 1911), one month after the injection, was +++. He gained ten pounds in weight, became more tidy in habits, quiet in manner, helped some with the ward work. At present he has been home on a visit for eight months, though he is far from being well mentally and requires some observation by relatives.

Case V.—D. B., male, white, aged 31 years; married, has three healthy children. Contracted syphilis at 21 years of age while in the army. Received some treatment with mercury. His psychosis was of ten months' duration when admitted to the Norristown State Hospital on March 21, 1910, and had commenced with depressive ideas and the belief that his lungs, brain, and other organs were missing or deformed. When admitted he was in an advanced stage of paresis; untidy and confused; pupils irregular in outline but reacted promptly to light; knee jerks diminished; tongue and facial muscles tremulous; speech slurring, writing characteristic; eye grounds normal. He was treated with mercurial inunctions for three months, and mixed treatment for three months longer with no apparent results.

A Wassermann reaction on the blood was ++++ and the spinal fluid was of low tension, slightly turbid; Noguchi weakly positive; Wassermann negative; cell count, 36 lymphocytes per cm. He was then anesthetized and given 0.4 gm. of salvarsan in the left median cephalic vein, 125 c.c. of salt solution being injected; rate of flow, 20 c.c. per minute. A slight rise of blood pressure was recorded. No change whatever followed the injection. Six weeks later a Wassermann on the blood was +++; the spinal fluid was clear, colorless; Noguchi positive; Wasserman +++; cell count, 36 lymphocytes per c.m. He was then given 0.6 gm. of salvarsan (May 1, 1911) in the left median cephalic vein, 140 c.c. of salt solution being injected (preceded by a spinal puncture). About half an hour afterward he became cyanotic and pulse feeble but he responded to stimulation. Within an hour he again showed



Case XI.—No anesthetic: Dose, 0.6 gm. in 150 c.c. salt solution; upper line systolic, lower diastolic pressure.

marked circulatory depression, but again improved under stimulation. No improvement in symptoms whatever has resulted. He is still in the hospital, untidy, destructive, and at times noisy. A

Wassermann reaction on the blood on February 21, 1912, was + +.

Case VI.—C. G. S., male, white, aged 45 years; married, seven children living and nine died in infancy. Moderate alcoholic; denied syphilis. Admitted to the Norristown State Hospital (April 20, 1908) with onset of psychosis one year before. Was quite grandiose, had delusions of infidelity, at times violent. Facial muscles relaxed and tremulous; tongue tremulous; Rhomberg sign present; knee jerks exaggerated; pupils equal and reacted sluggishly to light. Diagnosis: Paresis (expansive form).

A Wassermann on blood (February 2, 1911) was + + + +; spinal fluid (March 21, 1911) was of normal tension; turbid; Noguchi reaction strongly positive; Wassermann + + + +; cell count, 78 lymphocytes per c.m. He was then given 0.3 gm. of salvarsan in the left median cephalic vein (preceded by a spinal puncture). On account of the large amount of fat it was necessary to expose the vein to insert the needle, 95 c.c. of salt solution being injected, rate of flow being 20 c.c. per minute. Blood pressure showed little change; no unpleasant symptoms resulted, but the following day he removed the dressing and infected the wound, causing a rise of temperature to 99.8°. No improvement followed and patient is failing gradually. A Wassermann on the blood (April 27, 1911), four weeks after the injection, was + + +, and again (February 24, 1912) a Wassermann on the blood was + + +.

Case VII.—A. G., male, white, aged 37 years; divorced, no children. Alcoholic, with occasional excesses. Contracted syphilis at 27 years of age and was treated for a time. Admitted to the hospital September 18, 1910, with a psychosis of 18 months' duration. The onset was with a short period of depression followed by sudden development of many expansive delusions. He had muscular tremors and weakness; knee jerks exaggerated; pupils unequal, but reacted promptly to light; speech slurring; eye grounds normal. He had a six weeks' course of mercurial inunctions and then mixed treatment for six weeks, and examination of blood showed the Wassermann reaction (December 7, 1910) + +, a second examaination (December 18, 1911) + + +. Examination of the spinal fluid (March 21, 1911) showed it to be clear, colorless, of increased tension; Noguchi reaction positive; Wassermann + + +; cell count, 26 lymphocytes per c.m. Diagnosis: Paresis (expansive form).

He was then (March 21, 1911) given 0.3 gm. of salvarsan (preceded by a spinal puncture) in the left median cephalic vein, 150 c.c. of salt solution being injected, no anesthetic used, and no difficulty in inserting the needle. In half an hour he was nauseated and vomiting; that evening he had a temperature of 101°. For eight days he continued to have a slight rise of temperature and occasional headaches. For about six weeks before the injection he had shown some improvement and continued to improve for a month, when he was permitted to go home on a visit. At that time he was quiet, tidy in habits, and took an interest in the hospital amusements. He remained at home for eight months in a well-marked remission, and for a short time worked at his occupation as a cigar salesman, but was returned to the hospital December 18, 1911, in a noisy, expansive state. A Wassermann on the blood was + + + +. He failed rapidly and died February 1, 1912, from exhaustion of paresis.

Case VIII.—W. L. F., male, white, aged 32 years; married, one child. Contracted syphilis at 22 years of age and received some treatment. One year before admission he had a mild convulsion and for six months showed impaired memory. Before his admission his condition had been diagnosed as hysteria, and later as neurasthenia. When he came to the hospital he refused to talk or eat; resisted everything that was done for him; appeared in fear of personal injury; at times would weep; was filthy in habits; sat or stood in a stiff attitude; hands and feet cyanotic. Urine showed an occasional hyaline cast; peripheral arteries palpable; pupils equal and regular, reacted well to light. Tendon reflexes could not be tested on account of resistance of patient. At that time his condition strongly suggested the catatonic form of dementia præcox, but a Wassermann on the blood (April 27, 1911, was + + +, and the spinal fluid (May 25, 1911 was slightly blood tinged; Noguchi reaction positive; Wassermann + + + +; cell count, 36 lymphocytes per c.m., and a diagnosis of paresis was made. He was given mercurial inunctions for six weeks and after an interval of three weeks the course was repeated. On May 23, 1911, he was given 0.6 gm. of salvarsan in the left median basilic vein, no anesthetic being used, 160 c.c. of salt solution being injected. The injection apparently had no effect on the psychosis, and the patient died four months later (September 9, 1911) of exhaustion of paresis.

Case IX.—H. C. S., male, white, aged 38 years; married, no children; wife had three miscarriages. Moderate alcoholic. Contracted syphilis at 20 years of age and was treated for one year. Admitted to the hospital January 25, 1908, with the history that three years before he had been depressed, threatened suicide, had severe headache. About one year before admission he developed expansive delusions; memory became impaired, speech slurring, gait unsteady; he had a tremor of the tongue and facial muscles; knee jerks exaggerated; pupils equal and regular in outline but reacted sluggishly to light; moderate sclerosis of the peripheral arteries. He was given a six weeks' course of mercurial inunctions and on March 25, 1911, a Wassermann on the blood was + + and the spinal fluid was clear, colorless, low tension; Wassermann negative; Noguchi negative; cell count 2 lymphocytes per c.m. He was then given 0.6 gm. of salvarsan in the left median basilic vein, the vein being exposed under cocaine anesthesia as we had some difficulty in inserting the needle, 140 c.c. of salt solution being injected. There was slight flushing of the face but no headache or rise of temperature; the blood pressure changed little during the injection. A Wassermann on the blood (February 24, 1912) was still + + and his mental condition is gradually growing duller, with no benefit from the treatment. Diagnosis: Syphilitic pseudoparesis.

Case X.—L. G. K., male, white, aged 45 years; married, no children, wife had one miscarriage and one still birth. Denies syphilis, but has a suspicious scar. Admitted to the hospital March 12, 1910, with the onset about four years before, beginning with some depression, loss of flesh, sever headaches in frontal region. Had some insight at first but this was soon lost, and when he came to the hospital he had many delusions of persecution and

well-marked hallucinations of hearing. Knee jerks exaggerated; pupils unequal and irregular in outline, and reacted sluggishly to light. Tongue and facial muscles tremulous; peripheral arteries palpable. A Wassermann on the blood (April 5, 1911) was + + +, and he was given a six weeks' course of mercurial inunctions, followed by mixed treatment for four months. Examination of the spinal fluid (March 17, 1911) showed it to be clear, colorless, normal tension; Noguchi negative; cell count negative (acellular) and a later examination (October 6, 1911) showed the spinal fluid clear, slightly tinged with blood, normal tension; Noguchi negative; Wassermann negative; cell count negative. He was then given 0.6 gm. of salvarsan (October 30, 1911) in the left median cephalic vein, 150 c.c. of salt solution being injected; rate of flow, 20 c.c. per minute. No anesthetic was used and the injection was made without difficulty; there was some flushing of the face and fullness in the head with a slight fall in the blood pressure. Two hours later he became nauseated when lifting his head from the pillow, but this disappeared when he resumed the recumbent posture. The following morning (20 hours later) he complained of a strong metallic taste in his mouth. At present this patient is much improved physically and shows considerable mental improvement; he has gained ten pounds in weight; is more tidy about his person; helps well with any work he is requested to do, though he did no work before for many months; is good natured and respectful in language, though before was profane and obscene, and tells us he feels less "nervous" than he did before the injection. A Wassermann on the blood (March 1, 1912) was +. It might be advisable to give this man another injection at an early date. His diagnosis was cerebral syphilis.

Case XI.—G. L. C., male, white, aged 45 years; married, one healthy child. Alcoholic with occasional excesses. Contracted syphilis at 18 years of age and received some treatment. Admitted to the hospital October 12, 1911, with a history of the onset six months before with irritability due to loss of employment and overwork trying to establish a new business; he became quite grandiose, spent what money he had saved, was talkative and restless so that he was committed to a hospital, where he was confused for five weeks and then alternated between short periods of excitement and dullness with retardation in thought and action. At that time he strongly suggested the manic-depressive psychosis, but later paresis was suspected. When he came to us he remained in a rigid posture on his back, motionless and eyes wide open; he would not talk, but when questioned he became tearful and occasionally would slowly obey a command. Knee jerks were increased; pupils unequal but reacted promptly to light. A Wassermann on the blood was + + +, and he was given mixed treatment for four weeks and inunctions of mercury for four weeks longer. Examination of the spinal fluid (November 29, 1911) showed it to be clear, colorless, of high tension; Noguchi negative; Wassermann negative; cell count, 5 lymphocytes per c.m. He was then given 0.6 gm. of salvarsan in the left median basilic vein, no anesthetic being used, 150 c.c. of salt solution being injected. During the injection he had flushing of the face and some fulness in the head, there was little change in the blood pressure, but that evening he had slight rise of temperature and headache. He then had mercurial treatment until January 13, 1912, when a Wassermann on the blood was + + +. He has improved gradually and gained fifteen pounds in weight; his mental condition has also improved and he will probably recover entirely from the psychosis. A Wassermann on the blood (February 21, 1912) was —. Another examination of the blood will be made later to see if the Wassermann remains negative. His diagnosis we believe to be cerebral syphilis.

Case XII.—P. G., male, white, Italian, nine years in America, aged 30 years, single. Denies syphilis. Admitted to the hospital June 29, 1911, from the Eastern Penitentiary, the psychosis having developed in prison and was classed in the præcox group. Urine showed a trace of albumin and an occasional granular cast; he had tenderness over the stomach and a hard tumor extending downward and inward from the spleen two finger breadths below the costal margin; he had occasional attacks of vomiting and slight rise of temperature (100°). Examination of a test meal was practically negative. Examination of the blood showed hemoglobin 78 per cent., red cells 4,910,000, white 6,200; Widal negative; Wassermann + +. Examination for malarial plasmodia showed some pigment granules both outside and within the cells. On January 17, 1912, he was given 0.6 gm. of salvarsan in the left median cephalic vein, no anesthetic being used, 165 c.c. of salt solution being injected; rate of flow being 20 c.c. per minute. There was slight flushing of the face, but no unpleasant symptoms and no apparent improvement in the mental symptoms, but the vomiting has disappeared. An examination of the blood failed to show the pigment granules and a Wassermann (February 24, 1912) was +.

We are hardly justified in attempting to draw conclusions from an experience with so few cases treated, but a few points have attracted our notice:

(1) The intravenous administration of salvarsan in our cases has been a simple matter with no serious complications.

(2) There was very little change in the blood pressure even when 195 c.c. was injected.

(3) Two of our cases, whose psychoses were thought to be due to syphilis of the brain, were much improved by treatment; while two cases of paresis showed some temporary improvement. We doubt very much if paresis will be benefited by salvarsan.

(4) There is nothing in our experience to show the advantage of salvarsan over mercury in the treatment of syphilis.

LOCAL ANESTHETICS IN THE UPPER RESPIRATORY TRACT, INCLUDING THE ADRENALIN PREPARATIONS.*

By WOLFF FREUDENTHAL, M. D.,

NEW YORK.

All those who have done any surgical work in the days when there was no local anesthesia—that is, in the pre-cocaine era—will appreciate the great benefit derived by laryngologists, above all, from local anesthetics. Furthermore, just as the invention of Esmarch's bandage was of the greatest importance for bloodless operations on the extremities,

*Read before the Section on Laryngology of the N. Y. Academy of Medicine, March 27, 1912.

so the discovery of adrenalin meant for us in many instances a practically bloodless operation. Since all progress of whatever kind involves new dangers which we have to overcome, so it is with these new drugs, for there will be no doubt even in the mind of a beginner that, invaluable as these inventions are, they carry in their path many a danger. It is for us to decide where the danger point commences and how far we can go to produce anesthesia.

There are many ways of producing local anesthesia, as, for example, the local application of cold, compression of the nerves, etc. We shall not discuss these, but only that anesthesia which is produced by direct contact of chemicals with the mucosa. Generally speaking, all these chemicals are protoplasm poisons, which not only paralyze the sensitive nerve elements, but for a time also abolish the function of all living protoplasm without leaving a permanent effect. Consequently such drugs may produce general intoxication if they are absorbed quickly and in a concentrated solution. The degree of intoxication is proportional to the rapidity and intensity of the local anesthesia. It is an established fact that a small portion of the fluid always gets into a vein or lymph duct and may be carried quickly into the circulation. The larger portion, however, remains at the place of application and is absorbed slowly. The effect will therefore be so much more intense the slower the drug is absorbed from the area to which it is applied. An attempt has been made to prevent speedy absorption with results which will be discussed later.

Cocaine.—In the category of anesthetics we shall first mention cocaine, which was extracted from the leaves of erythroxylon coca in 1859 by Niemann and which was introduced into ophthalmology by Carl Koller, now of New York.

It is useless to describe to you the application of cocaine to the upper air tract, but I may be permitted to say here that acute intoxication after cocaine is not a very rare occurrence in our practice. One may merely notice a slight faintness, a small pulse, and heavy breathing. In more severe cases there are cold perspiration, dryness in the throat, a feeling of impending dissolution, hallucinations, laughter, unconsciousness, epileptiform attacks, coma, and finally paralysis of the respiratory center. Weigand found that in seventeen intoxications occurring after application of cocaine to the nasal mucosa there was no fatal result: in twelve poisonings after the aplication in the mouth and pharynx, two deaths resulted, and in eleven poisonings after anesthetizing the larynx, one death.

Chronic cocainism is nowadays quite rare after nasal applications, since we have learned how to avoid such occurrences. Occasionally, however, you hear of chronic cocaine poisoning which happens in people addicted to morphinism, when they use cocaine injections as a palliative. It is an unpleasant matter if you have to operate on a patient afflicted with chronic cocainism. The writer had one such case, a man forty-five years of age, on whom he operated for deviation of the septum. At that time we used Asch's method and generally put in the splints afterwards. I had operated in the afternoon, but was called out in the middle of the night, and when I got to the patient I saw him sitting in a chair leaning over a basin, a discharge constantly dripping from both his nostrils. The discharge had been so great that the splints had fallen out (fortunately there was no hemorrhage), but the patient was in an extremely nervous and irritable condition. I then found out that he had been in Europe two years previously and had received a snuff containing cocaine, which he had used daily since.

Cocaine has been combined with other substances, as, for example, antipyrin, 5 to 10 per cent., carbolic acid, and resorcin, but the addition of carbolic acid (4 per cent.) neither diminishes its toxicity nor does it increase the anesthetizing power. A mixture of pure cocaine with pure phenol (von Oefele) has been recommended by French authors, but Heinrich Braun of Leipsic properly rejects it because it affects the tissues very much and has produced gangrene.

Cocaine was for a long time the only local anesthetic in use, but very soon quite a number appeared, some of which were derived from other varieties of coca leaves, while others were purely synthetic. To the first group belongs

Tropacocaine.—This is an alkaloid derived from Java coca leaves. The solutions are stable and are not decomposed by sterilization. Unlike cocaine, tropacocaine does not bring about partial anemia of the mucosa, and perhaps for that reason alone it has not been introduced very much into our practice. Seifert observed several times profuse hemorrhages after the use of tropacocaine. It is hardly mentioned of late in any publication. Of the synthetic products I mention here

Novocaine.—This, too, can be sterilized and an injection of a 2.5 per cent. solution does not produce any pain nor any ill effect. Irritation occurs only when we use a 10 per cent. solution. It can readily be mixed with adrenalin. Experiments by Pouchet, and later on by Reclus, have demonstrated that here as elsewhere two factors are of importance in cases of intoxication: first, the degree of concentration, and secondly, the rapidity of absorption. Four centigrams of novocaine that had been dissolved in one c.c. of water were injected into an animal which soon died. In another animal one decigram, or 2½ times as much, dissolved in 15 cc. of water, was injected, and this animal remained alive. Piquand and Dreyfus injected into the ear of an animal a 1 per cent. solution of novocaine so that 5 c.c. of the fluid were introduced per minute. After three minutes, that is, after 15 centigrams had been injected, the animal died. When the rapidity of the injection was doubled the animal died after 9 centigrams were injected. When, on the other hand, the rapidity was diminished twofold, that is, when they took two minutes to inject 5 c.c., the animal died only after it had received 20 c.c. of the solution. Interesting as these experiments are for the question that chiefly concerns us, we must admit that novocaine is being used little in this country, although it is strongly recommended by some French and German authors.

Stovaine.—During the last few years stovaine has been widely discussed in laryngologic literature as well as in general surgery. It has been recommended as a substitute for cocaine, but stovaine, too, is a poison to the central nervous system and is seldom used nowadays in laryngology.

Alypin.—This drug has been lauded by several observers very highly. Others, however, assert that anesthesia produced by alypin is very weak. It may have a place in the amputation of the enlarged turbinated bodies, since it does not cause, as does cocaine, a very marked contraction of the hypertrophied turbinal. There are quite a number of other drugs recommended for local anesthesia

which, however, I do not care to discuss here, since their anesthetizing properties cannot be compared with those of cocaine, although their toxicity often is much less.

Orthoform.—Of far-reaching importance was the discovery of orthoform and two similar preparations. They are not very soluble and are not used in surgical practice, but as anesthetics and analgesics of long enduring action, especially on ulcerations of mucous membranes. They are of great value in such cases, and we can hardly see how any laryngologist can get along without the use of orthoform.

While cocaine produces oligemia, that is, a partial anemia of the mucosa, through contraction of the blood vessels, a new and wonderful remedy has been discovered which produces ischemia, that is, total anemia of the membranes and reduces the vitality of the membranes temporarily — characteristics which are so essential for the production of local anesthesia. This remedy is

Adrenalin.—In Germany they use the word "suprarenin" for the many preparations of the suprarenal bodies. Here in America, in England, and in France the term adrenalin is used mostly. As wonderful as the effect of this drug is, its application is sometimes dangerous. As this is one of the most important remedies in our daily practice, we will discuss it fully at this point.

In 1901 Takamine wrote that adrenalin did not have any toxic effect on the heart. This assertion was believed by every laryngologist, so far as I know, but it proved to be erroneous and misleading. There is no doubt that we have to deal here with a drug which, aside from its local action, may and does create a very toxic general effect if it is brought into the circulation in sufficient quantity and concentration. Carnot and Josserand have shown that it acts differently in different animals. Thus, one dog could stand, without any inconvenience whatsoever, the enormous dose of 0.5 miligram (intravenously) for each kilogram body weight, while another dog succumbed to a dose twenty-five times weaker. The same holds good for human beings. H. Braun and Doenitz injected adrenalin into themselves. When they used 0.5 miligram (equivalent to one-half cubic centimeter) general symptoms appeared, such as a sensation of depression, high pulse, and dizziness. When adrenalin was diluted ten times with a saline solution, they were able to inject double the quantity of it without producing any toxic symptoms. Furthermore, Braun added five drops of ordinary suprarenin solution to 100 c.c. of normal saline solution, that is, 1:600,000, and even with that dilution he had good results from injections.

Lermoyez and Aubertin have made many experiments on guinea pigs and have come to the conclusion that great care has to be taken in giving large doses of adrenalin on account of the dangers connected with it (edema of the lungs and hypertrophy of the heart muscles).

From these experiments and others previously mentioned we learn that one should never inject a large quantity of adrenalin into the circulation suddenly, nor should it be concentrated, or else toxic effects will appear. One may almost make it a rule that the slower we inject adrenalin and the more diluted it is, the less danger there will be.

When applied to the surface of the mucosa on a pledget of cotton or rubbed into the mucosa by-effects of adrenalin have not been seen.

Combination of Adrenalin with Other Anesthetics.—A. Froehlich and O. Loewi found that small doses of cocaine when used alone were very ineffective, but greatly increased the action of adrenalin, that is, in regard to its intensity and duration. *Vice versa,* it was found that a small addition of adrenalin to the cocaine was very effective and that it could be used well in non-operative cases. This last fact does not seem to be generally known. I am thinking now especially of local anesthesia for bronchoscopic work.

Recke investigated different substances of the cocaine group, especially holocain, acoin, nirvanin, and subcutin, and found that they could be combined effectively with suprarenin, but that the anesthetizing potency is slight compared to that of the cocaine-suprarenin mixture. Novocaine combines better with adrenalin, but after all it seems that cocaine is the only one of its group which does not abolish at all the vasoconstrictor properties of adrenalin.

Wherever we can stop bleeding immediately after the operation, we should *a priori* not expect any after hemorrhages. But in our work we cannot protect ourselves against that, first, because the mucosa has to be made as anemic as possible, and, secondly, because the sewing up of the wound and tying of vessels is not possible, for the simple reason that we are not able to see the blood vessels. That also may explain the occurrence of a hematoma after septum operations when tampons have been used on both sides of the nose. But this is only *àpropos.*

After having discussed the different drugs used to produce anesthesia let us consider now some of the more important operations performed in the upper air tract and their dangers. First, the *frontal sinus.* No less a man than Luc, of Paris, performed successfully the radical operation on the frontal sinus bilaterally under local anesthesia. The author has every reason to be satisfied with his success, but we are forced to believe that local anesthesia will never be used generally for such a large operation.

The operation most frequently performed within the nasal cavity nowadays is the so-called *submucous resection of the septum.* There are different ways of anesthetizing these parts, of which I shall mention first the perineural injections of anesthetics, recommended by several authors; then the application of pure cocaine to the mucosa. This method usually known as Freer's consists in swabbing the mucosa with cotton-wound applicators moistened in adrenalin and then passed through powdered cocaine. It gives an excellent and complete anesthesia, but some writers ascribe to it a distinct disadvantage, in that the percentage strength of the anesthetic is not accurately known. They recommend, first, that pledgets of cotton wool soaked in a 10 to 20 per cent. solution of cocaine, to which adrenalin is added, be packed against the septum. Then the septum should be painted over with the above solution and subsequently infiltrated with cocaine, plus adrenalin. Undoubtedly many laryngologists have not used Freer's method for fear of cocaine poisoning, yet the writer has applied it many times and never had any unpleasant accident from the application of pure cocaine in powder.

But as soon as we commenced infiltrating the tissues with cocaine plus adrenalin or with adrenalin alone, danger signals were seen, but not understood. When the patient was under a general anesthetic after the injection of adrenalin I have repeatedly

warned my assistants both in private and hospital practice as soon as I saw the patient suddenly blanch and show signs of respiratory difficulty. The first real accident with adrenalin was brought out in a discussion on Dr. Thomas J. Harris' paper (to be mentioned later on) by Dr. Thomas Hubbard, of Toledo, Ohio. Dr. Hubbard knew the details of the case and was kind enough to send them to me. The patient was a man about thirty years of age, healthy, except that he was very nervous from overwork. The operation was for removal of adhesions of hypertrophied turbinates to the septum and for deviated septum. Ether-chloroform anesthesia was given by a very expert man. "The patient took the anesthetic normally and was in excellent condition when the anesthetist told the operator to go ahead, and stopped the anesthetic, of course. Ten or twelve minims of adrenalin chloride, 1-1000, were injected into the turbinates, I presume, and a second injection was about to be given, or had been partly given, when the patient suddenly blanched, the heart stopped, and respiration gradually faded away.

"It is accepted here that adrenalin was the cause of death in the case reported and probably 12 or 15 minims were injected. Some escaped into the pharynx. In several discussions I have heard of so many narrow escapes that I am convinced that there is danger in its use in tissues that have rich blood supply, large venous channels, quick return to the heart, etc. It seems to me that if 5 minims (subcutaneously) will almost instantly check bronchial asthma, it is evidence of its extraordinary physiological activity."

So far Dr. Hubbard. A very similar accident occurred in the writer's own practice. A man twenty-six years of age, strong and well, asked to be put under general anesthesia for the correction of his deviated septum. That was done, and, while the writer was getting ready to operate, one of his assistants injected about ten drops of adrenalin, 1-1000. The assistant, having noticed in former operations that subperichondreal infiltration facilitates the detachment of the mucoperichondrium and mucoperiosteum, thought it best to raise the mucosa greatly by one strong injection of fluid. Unfortunately, the injection was not diluted. When I turned toward the patient a few seconds later, an extreme pallor appeared over the face and breathing seemed to have stopped immediately. There were four other very experienced general surgeons in the room, incidentally, and we all worked, together with our assistants, for a long time over this patient, but in vain.

I may add here that the accident occurred through the use of adrenalin in a system that was already somewhat depressed by chloroform. It was certainly not the action of chloroform that brought about the death, because in such cases we have not the exquisite and sudden pallor shown in all the accidents occurring after the use of adrenalin. Cocaine had not been used.

Other cases are reported in the literature which I mention here in order to bring them to your notice. Thus before the Society of German Surgeons Enderlen of Marburg reported briefly in a discussion the case of a weak woman, in whom he injected a very mild solution of cocaine, plus six to eight drops of adrenalin. The woman died and the death was attributed by Enderlen to the adrenalin.

Riballier injected five drops of suprarenin, 1,1000, into a child three months and a half old, whereupon a serious collapse occurred. The main law not to inject concentrated solutions was neglected here, too.

I have spoken to several other physicians about that matter and most of them recognize the danger of adrenalin injections. Dr. Wm. R. Butt of Philadelphia writes: "As the constitutional symptoms have been much more severe since using the adrenalin and cocaine mixture hypodermically than they were when cocaine alone was so used, and as they come on within a few seconds after the injection, I have for some time felt that they were due mostly to the adrenalin. When the adrenalin is rubbed on the mucous membrane or into the raw tissue with a cotton applicator the effect seems to be far less severe."

Dr. George B. Wood of Philadelphia believes that in about 10 per cent. or more of his patients in whom the drug has been applied in full strength secondary vasomotor relaxation occurs. An important paper on this subject was published only a few weeks ago (February 24) in the *British Medical Journal* by B. Seymour Jones. He proceeds as follows: Both nasal passages are sprayed with a 20 per cent. solution of cocaine, plus adrenalin *equal parts*. Secondly, both sides of the septum are thoroughly rubbed with cotton wool mounted on wool carriers soaked in the same solution of cocaine and adrenalin. He then injects a one-fifth of 1 per cent. solution of cocaine, to which adrenalin is added and he uses of adrenalin altogether twelve drops for the injections. He has had occasionally, like other observers, a collapse due to cocaine after fifteen minutes, but he writes: "In this connection I should like to interpolate a report of three cases showing the alarming effect of the sudden absorption of adrenalin on the septum, a fact due, in my opinion, to the action of adrenalin on the circulatory system depressed by chloroform and not the result of a nasal reflex."

The report of the three cases follows:

Case I.—A pale, anemic woman with feeble circulation was fairly deeply anesthetized before the submucous injection was thrown in. About a minute after this the patient blanched, became intensely pallid, respiration ceased, and the pupils suddenly dilated. She was promptly inverted, and after about twenty to thirty seconds of anxious waiting she gave a sighing respiration, then a second, and finally recommenced breathing.

Case II.—This occurred in a woman about a month later, almost in the same way, except that the untoward symptoms appeared earlier. Inversion restored her breathing, etc.

Case III.—This was a case of endonasal operation for antral suppuration. The patient was rather deeply anesthetized and ½ c.c. of normal saline with a few drops of adrenalin, 1-1000, was injected into the anterior end of the inferior turbinate. Within ten seconds respiration ceased, the pulse was suppressed, and the pupils widely dilated. She was inverted immediately and respiration was gradually restored.

Dr. Jones says: "The effect was attributable to adrenalin, as no cocaine had been used, and in the last case it occurred earlier owing to the wide venous spaces in which it was injected and more rapid absorption into the system." This last statement is quite in accord with my own conception of these cases as mentioned above. Dr. Jones was very lucky that his cases were not more serious.

We now come to the surgery of the *turbinated bodies*, and here I should like to warn again not to

inject any cocaine or adrenalin preparations, for the absorption is too quick and the dangers are too many. Many years ago the writer injected cocaine for certain other reasons. Not only violent headaches appeared, but also collapse, etc. Many observers have now given up injections into the turbinals. If we have to apply an anesthetic we may use any of these preparations on a pledget of cotton, and here perhaps the use of alypin is more advisable than that of cocaine, since it does not shrink the tissues to the same extent as the latter.

The *maxillary sinus.* In order to produce local anesthesia here different means are now in vogue. Thus submucous injections in the region of the middle meatus are being made effectively by several men and the radical operation performed.

Sturmann of Berlin and others use the following mixture:

Cocaini mur.....	1.0
Tr. iodi.....	
Ac. carbol. aa.....	0.3
Glycerini puriss.....	10.0
Aquæ q. s. ad.....	100.0

with a small addition of suprarenin.

Denker proceeds in the following manner: He paints the mucosa of the gingiva with a 10 to 20 per cent. solution of cocaine-suprarenin. Then he makes subperiosteal injections of the following solution: Novocaini, 1.0; normal saline, 100.0; adrenalin (1-1000) gtt., 80.0. Then he gradually applies the same solution as he proceeds. Altogether he uses 10 to 12 c.c. of that solution on one side and 20 c.c. for bilateral operation on the antrum without danger.

Munch of Paris uses regional anesthesia. He injects weak solutions of cocaine into the trunk of the nervus maxillaris superior at the base of the skull, where the nerve leaves the foramen rotundum and enters the fossa pterygomaxillaris. No untoward effects have been reported from injections for antral operations and the reason may be that the majority of these operations are done under general anesthesia, adrenalin being applied on pledgets of cotton only, and only a small percentage under local anesthesia by the injection method.

The next question we have to decide is, should we use local anesthesia for removal of *adenoids?* Ruprecht of Bremen uses a 1 per cent. cocaine-suprarenin spray for both nostrils. Then he applies six to eight cotton-wound probes dipped into a 10 per cent. alypin-suprarenin solution and applies them through the nose to the pharyngeal tonsil. The author is satisfied with this method. Leshure uses a similar method and others as well, but the writer fails to see the necessity or the advisability of local applications in adenectomies of young children. He never uses any.

Of great importance not only in our own specialty, but in medicine generally, is the *removal of tonsils.* Here again regional anesthesia is recommended by Yankauer by means of injection into the trunks of the nervus palatinus medius and posterior. This method has been tried by A. L. Weil of New Orleans, Broeckaert and others, and is being used by some men very satisfactorily.

Most operators, however, use cocaine-adrenalin injections into the crypts and around the tonsil. Others, as Leshure of New York and Laurens of Paris, first paint the tonsils with a "strong" solution of cocaine and then inject 1 to 2 per cent. cocaine, plus adrenalin (1-5000).

Ruprecht injects a 2 per cent. novocaine solution to which he adds 0.1 volume of suprarenin. Other operators use much weaker solutions of cocaine, plus adrenalin. To all of us, however, who have used these methods, it has often been a source of the greatest satisfaction to work in a bloodless field on an organ overrich in blood supply and frequently in an absolutely painless manner. Yet here again danger lurks. For unfortunately not everything is gold that glitters.

Several deaths have been recorded in the literature and perhaps many more have occurred unrecorded. The first case was reported by Dr. Thomas J. Harris of this city, who has had as much experience in removing tonsils as any of us. His report is as follows: "Man, aged thirty, in apparently good health, was given 1/60 of a grain of strychnine sulphate by the mouth. In about an hour 2 drams of 1/5 of 1 per cent. cocaine hydrochlorate solution, containing adrenalin chloride, were injected into the tonsils. This was followed in a few minutes by another injection, in all amounting to about 1/12 of a grain of cocaine and from 8 to 10 minims of a 1 to 1,000 adrenalin solution. Immediately after the second injection he complained of feeling ill, had a slight convulsion and turned ashy pale with profuse perspiration. His head was supported by an assistant and both tonsils were removed with the patient in an upright position. No hemorrhage followed the operation. The appearance of the patient following the operation, which did not require more than two or three minutes, was that of marked prostration and shock. He was therefore placed in the recumbent position, restoratives were administered, and artificial respiration was employed, but without result. Autopsy: Muscle wall of heart normal. Right auricle swollen and full of blood. All important organs of body apparently normal. Thymus enlarged."

We see from this report that the thymus has been found enlarged and the death was apparently attributed to that fact, but it seems to me beyond a doubt that since 8 to 10 minims of adrenalin had been injected, it was that drug that caused the death and nothing else. The 1/12 of a grain of cocaine given naturally helped to reduce the vitality. The presence of an enlarged thymus seems to me nothing but a mere coincidence. Dr. Harris is of the same opinion.

Another fatal case occurring here in New York, which has been described to me, was that of a young child of ten years, who was operated upon in the office of a physician, not a laryngologist, who injected as strong a solution of cocaine as 10 per cent., plus adrenalin, into the tonsils, whereupon the child died within a very few minutes. Of course, this last casualty is a result of gross carelessness and ignorance and can hardly be attributed to a rational application of cocaine or adrenalin. Such accidents can and should be avoided.

But simply alarming is a paper by Dr. Bryan DeF. Sheedy of this city, in which he reports three additional fatal cases all in his own practice.

Just think of it. Such an operation as tonsillectomy caused three deaths in a comparatively short time! Since not everything is clear to me in Dr. Sheedy's report I shall quote verbatim:

Case I.—"Man, aged twenty-five, in good health, except for an indisposition due to a slight attack of tonsillitis. About 1 dram of a solution made up of 1 grain of cocaine hydrochlorate and 1 dram adrenaline chloride 1 to 1,000 solution to 2 ounces of normal salt solution was injected in and around each

tonsil. The patient almost immediately became faint, broke into a profuse perspiration, became very pale; as he complained that he was about to faint he was placed in a reclining position, restoratives applied, and after a few minutes he was put in an upright position and both tonsils removed. No hemorrhage followed the operation. As he seemed to be in a profound shock, he was kept in a room adjoining the operating room for more than an hour. He then started for home and fell in the street about a block away, and before assistance arrived he was dead. Autopsy: Slight extravasation of blood around tonsil region. All important organs apparently normal. No glandular enlargement."

Case II.—"Man, aged forty-four, always enjoyed good health except for an attack of kidney trouble following scarlet fever when a boy. He called on his physician for removal of a large tonsil which had been giving some trouble. About 1 dram of a solution of cocaine hydrochlorate, 1 grain to the ounce, with from 7 to 10 minims of a 1 to 1,000 adrenalin chloride solution, was injected in and around the tonsil. As a part of the solution seemed to escape, in about fifteen minutes the injection was renewed. In less than three minutes' time after the second injection the patient became deathly pale, with no pulse at the wrist, and respiration became slow and labored, but improved slightly under a hypodermic of sulphate of strychnine, 1/30 grain. The head was supported by an assistant and the tonsil enucleated. The patient complained of marked weakness and prostration and was placed on a sofa, but before the surgeon could realize it there was no heart beat. All the ordinary restoratives were applied, but without success. No autopsy."

Case III.—"Young man, aged between twenty-five and thirty, had always enjoyed good health. (Patient had deviated septum with enlargement of faucial tonsils). Primary anesthesia was induced by a mixture of 3 parts of ether and 2 of chloroform. About 15 minims of a 1 to 1,000 adrenalin chloride solution was injected, the amount being divided into three insertions of the hypodermic needle. In half a minute after the last injection the patient's skin blanched as white as skin could, the respirations deepened and slowed down until they finally ceased. In one minute after the patient became deathly pale he was dead. No autopsy."

The last case is such a clear clinical picture of acute adrenalin intoxication that it could be given in a textbook as a classical example of it. Submucous injection of 15 minims of adrenalin; half a minute after the third insertion the skin blanches "as white as skin could," respirations deepen and—death in one minute. That is the type we have seen in the other cases and that we shall see again unless we change our methods. I use for injections a solution consisting of 1/5 of 1 per cent. cocaine, plus adrenalin (1:10,000). Maybe adrenalin could be used stronger, but in the present state of the question I do not feel safe in doing it.

I have enumerated all of these examples to show to the laryngologists, who are mostly concerned in this work, the danger of injecting large and concentrated doses of adrenalin into the tonsils or any other part of the body. I assert that right here in New York City at the Montefiore Home thousands of injections have been made subcutaneously without any fatal accident, but in all these cases adrenalin has been tried gradually, the dose being increased slowly. But in our practice it has proven to be dangerous, as conditions are different.

For that reason, perhaps, experiments have been made with another drug, a double salt, namely, *quinine and urea hydrochloride*. As this drug has been tried almost exclusively on the tonsils, I take the liberty of bringing it in at this place. Hertzler, Brewster, Rogers, S. Solis Cohen, Herzig, Sheedy and others have experimented with this drug. Fletcher Ingals claims that after an application of a 20 per cent. solution of the drug it took four times as long to produce anesthesia as with a 20 per cent. cocaine-suprarenalin solution. He recommends a 15 per cent. solution of urea-quinine combined with 5 per cent. cocaine in a solution of 1 to 2000 of suprarenalin. This solution he claims brought about anesthesia quicker than a 20 per cent. cocaine-suprarenalin solution and the anesthesia was more prolonged. J. Solis Cohen used it for the larynx and found it as good as cocaine. J. Gordon Wilson warns against its use. J. R. Winslow uses a 3 to 5 per cent. solution without adrenalin for injection into the tonsils. He has seen edema following its use after tonsillectomies, but no bad effects. B. R. Shurly, on the other hand, used it for the removal of tonsils, and frequently found a remarkable blue line following the line of injection. There was a considerable amount of swelling afterward. After using it in a few cases and hearing a report from the interior of his State that one of his colleagues had been sitting up all night attempting to control edema of the glottis following the use of a strong solution, he discontinued its use.

Chavanne states that it has not proven of great anesthetizing value, but he applies it in cases where for some reason or other he cannot use cocaine. And this for the present summarizes its use. At any rate, further experiments with quinine and its allied salts and urea should prove very interesting.

We come now to the *larynx*. Here I should like to draw attention again to the fact that small quantities of adrenalin added to cocaine or novocaine increase greatly the anesthetic power, and by remembering this fact we may save an unpleasant occurrence in laryngeal cases where we often have to use 20 per cent. solutions.

Very important was the discovery of anesthetics of long duration, especially orthoform, anesthesin and propesin. These drugs have proven to be of the greatest value when applied to ulcerations of the larynx, pharynx, and other parts of the upper air tract. But we again warn against the use of orthoform on the skin, as it is apt to produce an eczema that may spread all over the body. But for ulcerations on the mucosa it is an excellent remedy.

Spiess of Frankfort-on-Main says that in every case of inflammation the existing pain leads by reflex action to the formation of an exudate, etc., and that by removing the pain all other symptoms of inflammation are removed. I have been able to verify this statement frequently by applying any of the orthoform preparations to tuberculous ulcerations in the larynx which got well by the mere action of the drug removing the pain. For the use of the patient at home Hoffmann of Munich recommended a tube, one end of which the patient passes far into his mouth. Into the other end one of these preparations is put, and when the patient takes a deep inspiration it gets into the larynx. For the same purpose Yankauer recommended his syringe to be used by the patient himself in connection with the writer's orthoform emulsion. It is being used largely by many patients.

Other remedies for removal of pain in the larynx

are: (1) Bier's method of hyperemia modified by Dr. Polyak of Budapest. I personally have not seen any beneficial result from this method; (2) injections of alcohol into the superior laryngeal nerve, also recommended by Hoffmann. Quite a number of writers have experimented with that and have recommended it as an analgesic to be used in painful ulceration of the larynx. The writer has tried it many times. He found the injections somewhat painful, but without any danger and the analgesia lasts five days and more.

In conclusion I should like to repeat again that we have learned to be on our guard against toxic effects of cocaine and its derivatives. The statistics given today may help to warn laryngologists when they use that wonderful remedy, without which we could hardly exist, namely, adrenalin. I should like to close with the words of Nogué: "Nous pouvons donc écrire que l'adrénaline est un médicament qu'on doit administrer avec prudence dans tous les cas"—that is, that we have to use adrenalin with great care in all cases and I may add: especially when we make injections into the submucous tissues of the head.

1003 Madison Avenue.

THE MENTAL HYGIENE MOVEMENT.*

By WILLIAM L. RUSSELL, M.D.,

WHITE PLAINS, N. Y.

MEDICAL SUPERINTENDENT, BLOOMINGDALE HOSPITAL.

The Mental Hygiene Movement is an attempt to bring about broader social organization for dealing with disorders of the mind. Thus far the interest of society in these disorders relates almost entirely to providing institutional care for the grosser forms, and to the relation of mental disease to responsibility for crime. Little organized effort is made to deal with the less obvious though frequently the more dangerous types, or with the earlier stages of even curable cases, or to apply to the problem of prevention the known facts relating to causation. A broader and more efficient organization seems now to be possible. The remarkably rapid increase of the number of cases under institutional care, quite out of proportion to the increase in the general population, and the enormous appropriations required from State legislatures in providing for them, furnish a practical illustration and argument which have gone far to arouse in even the densest of the taxpayers some concern in regard to the possibilities of cure and prevention. The information concerning disorders of the mind, and the relation of mental states to various forms of ill health and their cure, which has, in varying degrees of accuracy and clearness, been spread abroad, has also helped to prepare the public to regard favorably attempts at greater efficiency in the organized methods. There is also available an increasing mass of scientific knowledge which may be applied to bringing these about.

In Europe the movement has not yet assumed as definite form as in this country, though various agencies are at work to accomplish the same objects. There is an International Committee, which was organized with a view to systematic effort, but it has not yet been in a position to begin active work. In this country the movement has with characteristic rapidity, advanced to the point of definite organization and there are already four principal centers of activity: Three of these are State organizations; the fourth is the National Committee for Mental Hygiene. This committee was formed in 1907, principally through the efforts of Mr. Clifford W. Beers of New Haven, and Dr. Meyer. There are 63 members, 23 of whom are physicians, several of them being members of this society. The announced objects of the committee are: (1) to work for the protection of the mental health of the public; (2) to help raise the standard of care of those threatened with mental disorder, or actually ill; (3) to promote the study of mental disorders in all their forms and relations, and to disseminate knowledge concerning their causes, treatment, and prevention; (4) to obtain from every source reliable data regarding conditions and methods of dealing with mental disorders; (5) to enlist the aid of the Federal Government so far as may seem desirable; (6) to coordinate the existing agencies and help organize in each State in the Union an allied but independent Society for Mental Hygiene.

Until quite recently active work has been limited by lack of means. These have now been provided, however, and plans for practical work must be made and carried out. The field is so wide, and the problems which must be dealt with are so complex, that it seems advisable to plan on broad lines with a view to stimulating and guiding, rather than actually undertaking to bring about specific practical improvements in local or State conditions or methods. The work will come under two divisions corresponding to the two main objects aimed at. One class of work will be for the purpose of bringing about improvements in the prevailing provision and methods for the care and treatment of the insane and other types of mental disorders. The other will have reference to prevention. For various reasons the first task that will be undertaken will have special reference to improvements in the present methods of dealing with mental disorders. Among these reasons may be mentioned that the funds available were given explicitly for the purpose of applying them to the amelioration of the condition of the insane. The other work of the committee can, however, and no doubt will, be carried on as ways and means are provided.

As a first step to bringing about improvements, a sub-committee of the National Committee has been appointed to make a study of the conditions in several States. This sub-committee has engaged an experienced physician and the work will be commenced at once. The study is not undertaken simply with a view to statistics or publicity, but is intended as a preliminary to constructive work in forming State and local organizations which, under the advice and guidance of the National Committee, may be led to take up the task of bringing about needed improvements.

Considerable time and labor have been spent by members of the committee, especially Dr. Hoch and Dr. Mabon, in formulating plans for the study of the conditions in certain States. The field is, however, too wide and the problem too complex to permit of more than a general working outline being followed. The work must be developed step by step as the way opens, though the main object aimed at must be clear and everything undertaken must contribute to its accomplishment; otherwise in such a wide field, and with the kind of material which must be worked with, it would be very easy to scatter our resources and to waste our energies in fruitless, and even in harmful, ways.

*Read at a meeting of the New York Psychiatrical Society, March 6, 1912.

The work which will be taken up at once includes: The preparation of summaries of the laws relating to insanity in every State; investigation of the provision for institutional care and treatment, and the methods and standards of administration in several States; also of the organized methods of dealing with cases of mental disorder which are not in institutions, and of the way in which mental disorders in delinquents are dealt with. The provision for instruction in psychiatry in the medical schools, and the attention which is given to the proper management of abnormal children in the public schools will also be ascertained. The facts will be obtained by inquiry and by observation by competent persons, and will be carefully studied with a view of turning them to account, in the most judicious and effective ways possible, towards bringing about organized State and local efforts to improve conditions. The investigations and studies planned will also furnish a foundation of facts relating to the whole situation in regard to mental disorders, which should be of great value in the further work of the committee.

Opinions will, no doubt, differ as to the value of the plan of work outlined, depending on the point of view and the relative importance which one or another may attach to the various activities in which a National Committee for Mental Hygiene may properly engage. And, in such a broad work there is sure to be differences of opinion. It may be said, however, that ever since the National Committee was organized all the plans of work proposed, of which I have knowledge, included among the first tasks to be undertaken, the collection of reliable information relating to the present conditions and methods in the care of the insane.

The State organizations which have been formed are the Mental Hygiene Committee of the New York Charities Aid Association; the Connecticut Society for Mental Hygiene and the Illinois Committee for Mental Hygiene. The New York Committee is a development in the work for the better care of the insane in which the State Charities Aid Association has been engaged for many years. In 1906 an After-Care Committee was formed to assist patients who had been discharged from the State hospitals. Later this committee broadened its activities so as to include work for the prevention of mental disease, and the title was changed to "The Committee on Prevention and After-Cure." In 1910 the title was again changed to the present one and a paid assistant secretary of the association was assigned to the work, and broader activities were undertaken.

The work is being developed along four lines: (1) Spreading abroad information relating to the more clearly understood causes of insanity. (2) Promoting the establishment of outpatient departments, psychiatric wards and departments in general hospitals, and psychiatric or observation hospitals with a view to better treatment of the early stages of mental disease. (3) Assisting individual cases who need advice and direction in obtaining proper treatment. (4) Promoting desirable legislation. Over 400,000 copies of pamphlets and circular letters have been distributed during the past year, and over twenty lay audiences have been addressed on the subject of the better management and prevention of mental disorders by the assistant secretary and by psychiatrists who are interested in the work.

At a recent meeting of the committee it was decided to appoint a social worker and to open a bureau of information to which applicants might be directed by charity workers and others. The experience of the past year has shown the need of these features. The sub-committee was appointed to take up the question of better provision for dealing with abnormal children in the public schools.

The Connecticut Society has about 600 members and employs a social worker who is engaged principally in furnishing advice and assistance to mental cases who are at large, or to patients who have been discharged from the State hospitals. The Illinois Committee employs four social workers and the work is like that in Connecticut. This committee is also working for the better provision for mental cases under observation with reference to the need of commitment.

To bring about greater efficiency in the organized methods of dealing with cases of mental disease is to take a step towards greater intelligence in the management of the whole problem, and should not be looked upon as something quite apart from work for prevention. The lines of direct approach in a campaign for the prevention of insanity are not very clearly defined. The problem is so complex that an attempt to deal with it directly seems almost like undertaking an attack on the causes of disease and misery in general. The methods employed must be principally educational in character. The few fairly definite issues, such as the relation of general paralysis to previous syphilis and of alcohol to certain psychoses, cannot be dealt with as directly and as simply as the acute infectious diseases or tuberculosis. What the mental hygiene organizations can do in regard to these is to disseminate information where it will do most good. The arguments employed in the efforts which are being made for venereal prophylaxis and for intelligent dealing with the alcohol problem will be strengthened if they include what is known concerning the relation of syphilis and alcohol to insanity.

A more special, and probably not an unpromising, field for mental hygiene may be found in applying what has been learned regarding the mechanism of the development of certain types of psychoses, and regarding the types of individuals in whom abnormal reactions are likely to occur, to bringing about better management in the training of children. The observations made in regard to heredity and the laws of its operation, may also furnish helpful data which can be employed in a campaign of education and may possibly be used also more directly in promoting effective action for the welfare of future generations.

The facts concerning the relations of immigration to the prevalence of insanity in this country may also be used in an effort to improve the methods employed for keeping out the unfit. Altogether there seems to be a considerable body of facts and information which can be used to good purpose by the organizations which have taken up work for the prevention of insanity and for more efficient methods in dealing with mental disease in individuals. The more intelligent public is already interested and ready for better organization and system in dealing with the problems at issue. If this interest is to be directed along sound and profitable lines the members of the medical profession, and more especially the psychiatrists, will have to take a hand in leading and informing.

THE LARGE INCISION AND THE REASON FOR IT.

By PERCY A. PERKINS, M.D.,

MEMPHIS, TENN.

ASSISTANT TO CHAIR OF SURGERY, UNIV. OF TENN.; ATTENDING SURGEON BAPTIST MEMORIAL HOSPITAL; ASSISTANT ATTENDING SURGEON, LUCY BRINKLEY HOSPITAL.

MUCH has been said and written recently advocating the large or roomy incision in abdominal work, but few have gone into details enough or given reasons why they prefer the large incision. So it shall be my object in this paper to present a few good reasons, collected from my own experience and the clinics of others, why the roomy incision should be the choice in the big majority of cases over the small one. Of course we can understand from an esthetic standpoint why the small incision should be very gratifying to the patient, but I do not think it should always suggest skill on the part of the operator.

1. With the large incision one can examine everything in the peritoneal cavity and also do better work and with greater speed. Often mistakes are made in diagnosis. I heard one of the leading surgeons of the country make the statement a few months ago that from 10 to 15 per cent. of the "exact diagnosis" were wrong. Now, granted that the average surgeon's percentage of error is at least 15 per cent., is not that reason enough in itself to justify a large incision?

Probably the mistake of making a small incision is more often made in doing appendectomies than any one thing. Now, how often do these cases come back (and not always to the same surgeon) complaining, and the surgeon wonders why the patient is still having trouble. The answer is this: he either made a mistake in his diagnosis or there was other additional trouble or pathology present which he did not find at the time. It is not always an easy matter to make a differential diagnosis between an appendix (chronic), gall-bladder, or stomach trouble. Often a diseased condition in one will give symptoms in the other. This appears logical enough, when we look at it from an embryological standpoint, as we know that the stomach, gall-bladder, and appendix are all derived from the same groove or primitive alimentary tract and so, of course, are all more or less in direct sympathy with one another. I have often seen cases in which an operation was done for an appendicitis, and after a practically normal appendix had been removed and a further examination had been made, gallstones were found. And again I have seen appendix trouble mistaken for a gastric or duodenal ulcer, salpingitis, etc., and *vice versa*. McCarthy in an examination of 2,000 appendices found 8.7 per cent. associated with cholecystitis. Also 52 per cent. of 175 cases of cholecystitis with and without stones, gave histories of pain in the region of the appendix.

Out of 1,244 women operated on by the Mayo brothers for uterine myomota, 7.1 per cent. had gallstones. Statistics also show that 25 per cent. of all women over 60 years of age have gallstones. In 5 per cent. of autopsies gallstones are found, and in adults alone 10 per cent.

Another condition that is not uncommonly found is a Lane's kink. This condition is usually found in the ileum, although not always. As a rule one sees the ileum rotated on its long axis and fixed upon the mesentery in such a way as to lessen its lumen. This condition may be inflammatory or congenital in origin and is often the cause of chronic constipation, etc. Now, it can be readily seen that it would be impossible to find and correct these conditions if one were working through a small incision, and yet if they exist and have not been corrected, injustice has been done the patient, for he has not been cured and in all probability will be subjected to a second operation.

2. Another mistake, and probably the most important of all, is in removing ovarian cysts through small incisions. In olden days the operator took great pride in removing these cysts, no matter what size, through very small openings; first tapping the tumor and then drawing off all the fluid and pulling the collapsed affair through the tiny opening.

We know now that this is a very dangerous procedure. Statistics show that 16⅔ per cent. of these cysts are malignant. So one can readily see the danger of opening these tumors before removing, because it is practically impossible to keep the fluid from escaping back into the peritoneal cavity or contaminating the edges of the incision through the abdominal wall. If this does happen, we are sure to get a recurrence (implantation, carcinoma, or sarcoma). Now, there is only one way to avoid this and that is to remove the tumor *en masse*, even if it is necessary to extend the incision from ensiform to symphysis pubis. Of course, in certain "selected" cases, especially in young women, a surgeon might be justified in operating through a small incision.

The most common reasons given against the large incision are: (1) Prolonged recovery; (2) liability of hernia.

The answer to the first is that, with the present day aseptic technique and a proper care in closure of the wound, the patient should be up in 14 days.

In answer to the second it may be said that hernias are very rare; in fact the best men say that they never see one following a clean case. It is not necessary for the patient to wear an abdominal binder or supporter after getting up.

Now, the reasons why the large incision should be used are:

1. Safety.
2. Speed.
3. Surety (of diagnosis).
4. Success.

1112 MEMPHIS TRUST BUILDING.
May, 1912.

Postinfluenzal Paralysis of the Soft Palate.—A. Wylie reports the case of a male, aged 30, who had always been a healthy man. In the second week of December he was laid up for ten days with an influenzal cold, congested throat, and fever. He returned to work before Christmas time, feeling weak, but otherwise well. A few days later fluids regurgitated through his nose; solids he could swallow quite easily. By January 7 his speech became nasal or cleft palate in character and he found that he had to hold his nose in order to make himself heard. No specific history. No diphtheritic symptoms and, although a culture had been taken, no Klebs-Loeffler bacilli had been diagnosed. On examination a bilateral paralysis of the soft palate was seen; sensibility was to a slight degree diminished. Except for a congestion and enlargement of the posterior end of the right inferior turbinal the nasopharynx appeared normal. The movements of the tongue, larynx and sternomastoid muscle were normal. Tonics of iron and strychnine improved the condition. The author considers it a case of postinfluenzal neuritis simulating the condition more commonly found as a sequela of diphtheria. —*Proceedings of the Royal Society of Medicine.*

THE MENACE OF POLIOMYELITIS.

For the past five years the increasing prevalence of poliomyelitis during the months of July, August, and September directs attention to the probability of the recrudescence of this disease during the present summer. One of the most significant and ominous facts about poliomyelitis has been its extraordinary increase and wide diffusion in the United States, to an extent far greater than in any other part of the world. From 1881 to 1900 there were reported in this country 200 cases of the epidemic form of the disease; from 1900 to 1904 there were reported 100 cases; from 1905 to 1909, the number of cases rose to 5,400; and in the single year 1910, the appalling figure of 9,000 represented the newer victims of this insidious scourge. The wide diffusion of the latter was shown in its presence in 43 States of the Union during the last-mentioned year. The rapid evolution of poliomyelitis presents a sharp contrast to the growth of this disease in Europe, in which at no time have there been reported more than 2,000 cases in one year, as in the Swedish epidemic of 1905. The phenomenal spread of poliomyelitis demands now more than ever the most energetic action on the part of public health authorities in enforcing the necessary quarantine and in studying the laws governing the diffusion of this disease. As a model of this work may be mentioned the investigation conducted by the Massachusetts State Board of Health* as to the prevalence of poliomyelitis in that State during 1910, and as to its etiology and mode of transmission. The report of this investigation includes a careful epidemiological survey of the cities of Fall River and Springfield, which were marked epidemic centers.

One of the most important parts of this report is the analysis of poliomyelitis with special reference to its occurrence in Massachusetts from 1907 to 1910, by R. W. Lovett and M. W. Richardson. The incidence of the cases indicates an apparent two-year periodicity, which corresponds to a similar behavior in other parts of the world. Small towns and cities seem to be the ones most affected by the disease, which attacks, however, all classes, rich and poor, in the cities and in the country, in tenements and in detached houses. There is no longer any doubt as to the transmissibility, which may be by direct contact with the sick individual, through the intermediation of the healthy human carrier, or by means of dust, fomites, insect parasites, or domestic animals. The relative transmissibility of poliomyelitis, when compared with other infectious diseases in the same territory, was investigated by Hill in the State of Minnesota. This observer found that of persons known to have been exposed to various infections the percentage contracting the disease was as follows: scarlet fever, 22; diphtheria, 17; infantile paralysis, 6. Where one case existed in a family other cases were found in the same family to the following extent: scarlet fever, 40 per cent.; typhoid fever, 30 per cent.; diphtheria, 29 per cent., and poliomyelitis, 17 per cent. These figures indicate that the danger of contagion, while less than in the case of the other infectious diseases, is nevertheless a real one, and demands, as in the latter, the institution of an efficient quarantine. The undoubted existence of abortive cases, *i. e.* those in which paralysis does not supervene, renders impossible the determination of the exact degree of communicability of this disease.

The most important advance that has been made in the recent study of poliomyelitis, apart from its experimental production in monkeys, has been the demonstration that these abortive types can be recognized clinically, and that even the ordinary cases can be diagnosed during the preparalytic stage. Forming a fitting complement to the epidemiological and experimental studies of this disease, the clinical study now occupies the center of the stage. Exceptional opportunities for this study presented themselves during the summer of 1911 at the Hospital of the Rockefeller Institute at which seventy-one cases were under close observation, in addition to ninety cases that were treated in the dispensary. The interesting results of this study are set forth in an elaborate monograph by F. W. Peabody, G. Draper, and A. R. Dochez.* One of the first points attacked was that of the efficacy of the "neutralization test," which is based upon the discovery by Levaditi and Landsteiner, Römer and Joseph, and Flexner and Lewis that the serum of recovered monkeys is able to protect normal animals against fatal doses of the virus; and the further discovery by Netter and Levaditi, Flexner and Lewis, and Anderson and Frost that the serum of recovered human cases possesses the same protective property. The investigators of the Hospital of the Rockefeller Institute employed this test in the case of normal, suspected, and poliomyelitic sera. The results showed that the test could not be considered to give specific evidence as to whether a given individual has or has not suffered from a previous attack of poliomyelitis. In typical instances of poliomyelitis the serum of the infected individual probably always contains, after a certain interval, protective bodies. In spite

*"Infantile Paralysis in Massachusetts during 1910, together with reports of special investigations made in 1911 bearing upon the etiology of the disease and the method of its transmission." Reprinted from the Monthly Bulletins of the Massachusetts State Board of Health for 1911. Boston: 1912.

*"A Clinical Study of Acute Poliomyelitis," by Francis W. Peabody, M.D., George Draper, M.D., and A. R. Dochez, M. D. "Monographs of the Rockefeller Institute for Medical Research," No. 4.

of the irregular results obtained with normal sera, the specificity of the test cannot as yet be ruled out. In the case of an apparently normal person whose serum protects, the possibility is suggested that he may have suffered from an unrecognized abortive attack of the disease.

Peabody, Draper, and Dochez suggest a new and simpler classification of poliomyelitis. The generally accepted classification is that of Wickman, who recognizes the following eight forms: the spinal form, the form resembling Landry's paralysis, the bulbar or pontine form, the encephalitic form, the ataxic form, the neuritic form, the meningeal form, and the abortive cases. It is pointed out that this classification is based neither on pathological anatomy nor on clinical symptomatology, but on a mixture of the two; the spinal, bulbar, and encephalitic forms being anatomical forms, while the neuritic, the meningeal, and the ataxic forms are essentially symptomatic forms. The authors would substitute for this classification one in which three groups of cases are recognized: the first consists of the abortive cases, in which paralysis does not occur; the second is the cerebral group, containing the rare cases with involvement of the upper motor neurons and a resulting spastic paralysis as the chief manifestation; the third or bulbospinal group is the largest and includes all the cases in which lesions are present in the lower motor neurons and in which flaccid paralysis occurs.

The fact is emphasized that poliomyelitis is not synonymous with paralysis, and that the rôle played by this secondary symptom in the clinical history of the disease is becoming relatively less important. This conception is based upon the modern knowledge that poliomyelitis is a general infectious disease, in which the entire organism is affected, although in most instances, as far as we are at present aware, paralysis is the most prominent manifestation. At any rate the recognition of abortive cases is strengthened by this conception. Wickman believed that the abortive cases represented from 25 to 56 per cent. of the total incidence of the disease, while Müller has regarded the unparalyzed cases as even outnumbering the paralyzed ones.

The recognition of the abortive cases is a matter of eminent practical importance from the viewpoint of maintaining an efficient prophylaxis. Wickman classified these cases into those which run the course of a general infection, those in which meningeal irritation is especially marked, those in which pain is a pronounced symptom, and those with gastrointestinal irritation. A few of the abortive cases have been studied at the Hospital of the Rockefeller Institute. These show some degree of transient muscular weakness, which in two instances was most pronounced about the pelvis. Irritability and drowsiness are frequently present. Pain is a very common symptom and may be muscular or neuritic, often in the neck or back, or in the form of headache. The abortive cases closely resemble influenza. Blood and spinal fluid may show characteristic changes. Such cases occurring during the summer, and particularly if there are cases of poliomyelitis in the neighborhood, should be regarded with suspicion and quarantined.

As regards the blood changes in this disease, the authors have noted a constant and marked leucocytosis with an increase of polymorphonuclears of 10 to 15 per cent. and diminution of lymphocytes of 15 to 20 per cent. Examination of the cerebrospinal fluid reveals the following changes: During the early days of the disease and before the onset of paralysis, there is an increased cell count with a low or normal globulin content. During this stage the polymorphonuclear cells may amount to 90 per cent. of the total, but most fluids show almost exclusively lymphocytes and large mononuclear cells. After the first two weeks the cell count usually drops to normal or nearly so, and there is frequently an increase in the globulin content. The spinal fluid reduces Fehling's solution. These changes while not specific are of considerable value as an aid to diagnosis in the preparalytic stage and in abortive cases.

Of eminent importance to the general practitioner is the ability to recognize poliomyelitis during the prodromal stage, for it is only during this stage that the institution of proper measures may serve to arrest the progress and prevent some of the dire consequences of the disease. While the symptoms preceding the onset of paralysis are generally not different from those found in other infectious diseases, there are certain specific symptoms that should put one on guard. Müller, who studied the epidemic in Hesse-Nassau, found that the majority of cases had symptoms referable to the respiratory tract, and that profuse sweating was one of the cardinal symptoms of the early stage of the disease. Peabody, Draper, and Dochez could not confirm this observation except to the extent that sweating is a common accompaniment of fever in children. They emphasize, however, the importance of drowsiness which is associated with the fever. Frequently irritability replaces the drowsiness, and is closely related to the hyperesthesia which Müller regards as one of the three cardinal symptoms of the prodromal period. Pain, both spontaneous and that produced by passive motion, is also a prominent symptom of this stage. Muscular weakness is frequently observed. Muscular twitchings and tremors were present in several of the authors' cases. Respiratory symptoms were found in a few of these cases, but not to the extent of 50 per cent. as reported in the Hesse-Nassau epidemic. Gastric symptoms, such as anorexia and nausea, were very frequently observed. Of all the prodromal symptoms hyperesthesia was the most characteristic.

The Rockefeller Institute report represents one of the most valuable recent studies of the clinical manifestations of poliomyelitis, and merits careful study by all practitioners who will unfortunately be called upon more and more during coming years to cope with this grim enemy of early childhood.

THE MARINE HOSPITAL SERVICE SALARIES.

In the Medical Record of March 23, 1912, attention was drawn to Senate Bill No. 2117, known as the Personnel Bill, designed to equalize the salaries of the Public Health and Marine Hospital Service with those of the army and navy medical corps.

The merits of this bill were pointed out and its passage by the House of Representatives was strongly urged. In 1889 substantial advances were made in the salaries of the commissioned officers of the army, navy, and revenue cutter service. The officers of the Public Health and Marine Hospital Service constituting only 1.5 per cent. of all the commissioned officers of the United States alone received no advance.

The essential features of the present personnel bill were included in a bill (S. 6101) passed by the Senate in the first session of the 60th Congress, but it failed in the House. In the third session of the 61st Congress a similar measure (H. R. 30,292) passed the House, but died in the Senate. In the same session the Senate adopted an amendment to the Sundry Civil Bill, containing the same features and salary advances, but it was stricken out in conference. Thus the Senate and House have both passed favorably upon the provisions of this measure, but at different times, and the Public Health Service has been buffeted back and forth, and suffered a great injustice.

Physicians least of all need any argument to prove that the Public Health and Marine Hospital Service abundantly deserves hearty support and intelligent cooperation from the public, and especially from Congress. It operates all quarantine stations with few exceptions, and should operate all, and is our chief bulwark against plague, cholera, and yellow fever. In the yellow fever epidemic in New Orleans in 1905, the service saved the nation over a hundred million dollars, as compared with the similar condition in 1878, when the Mississippi Valley sustained a loss of more than a hundred millions from yellow fever. The salaries of the service officers to date since the reorganization of 1870 have totaled under $8,000,000. The expenditure of several millions for a single new battleship is an extravagant and problematic advantage compared to the appropriation of $100,000 to increase the efficiency of the only national defence we have against epidemic disease and the only national agency concerned primarily with improving public health and sanitation in this country. It is scarcely necessary to mention the 23 marine hospitals and 120 other relief stations maintained by the service for the benefit of American seamen. The Hygienic Laboratory at Washington has made great advances in our knowledge of epidemic diseases and in the solution of numerous hygienic problems. The demonstration of the identity of Brill's disease and typhus fever, and the experimental transmission of measles to monkeys are very recent contributions from this laboratory. The service has given the Philippines the best health protection they ever had. The medical examination of all immigrants is likewise conducted by officers of this service.

The report of the Committee on Public Health and National Quarantine to the Senate when that body passed the Personnel Bill stated that the present salaries were believed inadequate to preserve the efficiency of the service or to attract desirable men to it as vacancies occurred. Especially is this true because of the greater inducements offered in the army and navy medical corps, for service no more responsible or onerous, and scarcely so hazardous.

The Personnel Bill in no way affects any other public health legislation, nor does it in the remotest degree have any bearing on the creation of a national department of health. It simply does tardy justice to the officers of the Public Health Service in the matter of a salary commensurate with the importance and dignity of the duties they perform and the responsibilities they assume. The bill as it passed the Senate has been reported favorably to the House by the Committee on Interstate and Foreign Commerce. A few weeks ago it was brought up in the House on the "unanimous consent" calendar, but objection to its passage was made by Mr. Mann. Now as Congress draws nearer to adjournment, there is danger that the bill will not be passed, in spite of the fact that a majority of the congressmen undoubtedly favor its passage. For the continued efficiency of the Public Health Service it is imperative that the House of Representatives pass this bill. Every consideration of justice and national honor, as well as of regard for public health and hygiene, urges that it be passed. Politics must no longer stand in the way. The Personnel Bill should be adopted by the House before the adjournment of Congress.

THE YOUNG AND SEXUAL HYGIENE.

The question of the necessity for education of the young in sexual hygiene has absolutely forced itself upon the attention of the community. For years it has been well known that there was crying need for such education, but owing to the prudery, inbred and instinctive, of the so-called Anglo-Saxon race, the matter has been blinked at and shelved. Of recent years, however, a new spirit appears to be animating the English speaking peoples in this respect, and now it is generally allowed that it is strongly advisable to instruct the young in sexual hygiene, and that the subject should no longer be taboo. Also, it is to be noted, even the conservative British physicians are taking up the matter and arguing that the time is ripe for theories in this direction to be put into practice. Dr. Eric Pritchard writes in the *Medical Press and Circular*, June 5, 1912, in favor of the instruction of the young in sexual hygiene. He points out that the reason why children should be taught sexual morality is connected partly with their own individual interests, and partly with the wider interests of race preservation. For the child's own sake it is desirable that it should have an intelligent comprehension of the physiological processes of life, including that of reproduction, in order that at the time of puberty it may understand the significance of those radical changes which herald its physico-sexual maturity. Such knowledge is necessary in order that the psychological shock of a too rude awakening may be avoided at this crisis in the child's life, and in order that it may be armed at a somewhat later period against the consequences of venereal diseases, and of physical and moral corruption.

With regard to a most important point, that of the best time to begin sexual instruction, Pritchard thinks that it would be advisable to confine our energies to the instruction of children who are about to leave school and are going out into the world with all its dangers and temptations. Possibly Brit-

ish children leave school at an earlier age than they do in this country, or else they must be much more innocent than American children. Here, it is safe to say, school children who do not know the broad facts of sex life and reproduction long before their school life is ended are few indeed, and Pritchard would be too late with his instruction; he would find the field already grown up in weeds with little room for the seeds of morality he might sow to take root. We do not mean to say all children of this age are corrupt—indeed, few are, but if those few are to be saved by knowledge their instruction must be begun at an early age; the end of school life is too late. More emphatic is his opinion that it is of equal importance that teachers and parents should likewise be taught many of the strange manifestations of the sexual instinct of which at the present time they are in complete ignorance. They do not know what to expect, what to anticipate, or how to recognize the symptoms when they appear, and are consequently ill-adapted to train the children under their direction. In conclusion, Pritchard suggests that we should all make an effort to face the difficulties of the situation and free ourselves of that shamed-faced self-consciousness which has in the past enveiled the whole question with an atmosphere of unnatural and artificial indecency—indecency which does not exist except in the imagination. Teachers, parents, and physicians should divest themselves of this false conception and attempt to arrive at some satisfactory solution of the problem.

The Role of Bulbar Compression in the Production of Syringomyelia.

That the phenomena of excavation of the gray matter of the spinal cord may result from a slowly developing neoplasm pressing upon the cord is clearly demonstrated in a case reported by J. Lhermitte and P. Boveri in *La Riforma Medica,* June 8, 1912. The clinical history was as follows: A man thirty-four years of age began to develop at the age of thirty a progressive paresis of the lower limbs, an atrophy of the right side of the tongue, and a slight atrophy of the thenar and hypothenar eminences. Sensation was not affected, the reflexes of the lower limbs were greatly exaggerated, and Babinsky's sign was positive on both sides. The pulse was normal, but cyanosis of the face and a slight dyspnea were present. Death occurred suddenly as the result of respiratory failure. Autopsy revealed an exostosis that had developed from the basilar process of the occipital bone, and that had pressed deeply into the posteromedian portion of the medulla oblongata. This pressure had resulted in the formation of a spinal cavity which had extended as far down as the level of the third cervical vertebra. The mechanism of the production of this form of slowly developing syringomyela was studied experimentally in the dog. It was found that the introduction, following laminectomy, of a bit of laminaria at the level of the seventh dorsal segment caused an excavation of the spinal gray matter similar to that observed in the case reported. The authors conclude that compression of the median and dorsal portion of the medulla may result in the production of a myelomalacia limited to the central and posterior portions of the gray matter, and accompanied by the elimination of the necrotic products.

Preserved Human Milk.

In this country the wet nurse is not a widely recognized institution in child conservation, nor perhaps is she likely to be such. Hence the problem of preserving her milk may strike American readers as somewhat novel. But in various European lands where she has always been regarded as a vital necessity, and where domestic economy is much more exploited than in wasteful America, it is not strange that there should always have been some effort, even if sporadic and episodical, to economize in breast milk, as in any other essential commodity. This subject was debated at a very recent session of the Verein für innere Medizin und Kinderheilkunde, Berlin (*Berliner klinische Wochenschrift,* June 17). It would appear that the prevalent custom in foundling asylums and maternities has simply been to place the excess of breast milk, as obtained by the breast pump, upon ice. Dr. Peiser, the reader of the paper, called attention to the fact that in institutions a superabundance of breast milk may alternate with a famine in the same. He advocated the addition to the milk of a few drops of hydrogen peroxide, the idea having been borrowed from the Budde method used for the conservation of cow's milk. In reply to the objection that simple conservation in the icebox would answer all requirements, Dr. Peiser says breast milk may be kept for six days with ice alone, but with the addition of the chemical preservative it will keep considerably longer.

News of the Week.

School Hygiene Bureau.—A delegation of physicians headed by Dr. James A. Miller appeared before the Committee on Elementary Schools of the New York Board of Education on July 9, and asked that the Board establish a Bureau of Hygiene. Dr. Miller, who is secretary of the Committee on Public Health of the Academy of Medicine, stated that the committee had found that the supervision of matters pertaining to the sanitary condition of the schools and the health of the children was divided between the committees on buildings, on the care of buildings and on supplies, and the city superintendent, and that it was their belief that there should be a direct localization of responsibility. He therefore advocated a bureau of hygiene with a physician at its head. Although ably supported in his arguments by the other members of the delegation, Dr. Miller's suggestions did not appear to meet with the approval of the committee, which considered that the establishment of such a bureau was unnecessary. The committee and the physicians did agree, however, that there should be a larger force of physicians for the examination of defective children and the committee declared its intention of asking for the appointment of at least six in addition to the present corps.

New Volunteer Hospital.—A site on the corner of Beekman and Water streets, New York, has been purchased for the erection of a new home for the Volunteer Hospital which for some time has been very much cramped in its old quarters on Gold street. The new building will be five stories high, and will have a roof garden. It is expected that it will be ready for occupancy on January 1, 1913.

Goldfish vs. Mosquito.—Acting on the theory that minnows destroy the larvæ of mosquitos the Illinois Central Railroad has announced its intention of stocking every stagnant pool on its lines with

goldfish, the only minnow which can live in stagnant water. It is hoped that in a short time the mosquitos will have been entirely eradicated by the hardy minnows. The railroad has asked the cooperation of the various State hatcheries along its lines and of the Federal hatcheries, but if this is not given it will establish its own hatcheries and stock the pools itself.

Experiment in Municipal Ownership.—The City of St. Louis will shortly undertake an experiment of interest to laboratory workers when it will establish on the grounds of the City Infirmary a farm for raising guinea-pigs and rabbits for the use of the various medical institutions of the city. It is believed that the cost of raising the animals will be less than the cost of purchasing them and that a more plentiful and satisfactory supply will be available than under the present conditions of dependence upon dealers.

Kunitzer Injunction Ended.—Justice Gerard of New York recently denied the application of Dr. Robert Kunitzer for a permanent injunction restraining the New York County Medical Society from taking a second vote on the charges brought against him, and on which the Society some time ago ordered his expulsion. Justice Gérard had had the application before him since May 29, when he heard the argument of counsel. This leaves the Society free for the present to act on the charges, but it is thought that Dr. Kunitzer will probably carry the matter to a higher court.

Maxims for Mothers.—The New York Diet Kitchen Association on July 8 opened a new branch milk station, to be known as the Tuck kitchen, where milk for infants and invalids will be supplied. In the milk stations throughout the tenement districts the following maxims for mothers have been posted: "Take your baby to a milk station and you won't have to take it to an undertaker. Don't wait until baby is sick; the milk station keeps baby well. Don't feed baby every time he cries; learn to read baby's cry at the milk station. Good air is baby's cheapest medicine; at the milk station you can learn how to get it in the easiest way. The milk station doesn't sell patent babies' foods; don't use them except when the doctor tells you to. Keep baby cool, clean and quiet; if you won't, the milk station can't help you."

Infant Mortality.—It is stated that during the first week of this July there were in New York 267 deaths of infants under one year of age, or 80 less than during the same week of last year, and that for the past six months the number of deaths has been 416 less than for the same period of 1911.

Col. William C. Gorgas, chief sanitary officer of the Isthmian Canal Commission, has refused an offer of the chairmanship of the Boston Board of Health, with the statement that while his work on the Isthmus is nearly over he feels that it is his duty to remain until the actual completion of the canal. The Mayor had previously offered the appointment to Dr. Wiley, who declined. Why not draw upon home talent? Boston has many good sanitarians, some one of whom might be induced to look after the health of his fellow-citizens for $5,000 a year.

Harvard Medical School.—The Board of Overseers of Harvard College have announced the following appointments to the Harvard Medical School faculty, to take effect on September 1: Dr. Howard Augustus Lothrop to be assistant professor of surgery; Dr. John Lewis Bremer to be assistant professor of histology; Dr. Marshall Fabyan to be instructor of comparative pathology; and Dr. Herman Frank Vickery to be instructor in clinical medicine, the last being a reappointment.

No Extra Pay for City Officers.—The Appellate Division of the Supreme Court of New York recently handed down a decision reversing a judgment for $2,140 awarded by a jury to Coroner's Physician Otto H. Schultze of New York, who had testified as a pathological expert in the Patrick murder trial and other criminal cases. The court held that by accepting the appointment as coroner's physician Dr. Schultze became a city officer and was prohibited from recovering for any services to the city or county while holding such position.

Centenarian Dead.—The oldest resident of Massachusetts, Mrs. Catherine Snay, died at Oxford in that State on July 10, from heat prostration, aged 106 years. She retained her mental faculties until the end, in spite or because of the fact that she was an inveterate pipe smoker.

New Coroner for Bronx.—Governor Dix on July 10 appointed Jerome F. Healy as coroner for the Borough of the Bronx, New York, to succeed Coroner Albert Schwannecke who died a short time ago from injuries received in the performance of his duties. Coroner Healy ran against Coroner Schwannecke at the time the latter was elected to office three years ago.

Repeat Carrel's Experiment.—The French Academy of Medicine, which has appeared to be rather sceptical of the reports made before it as to the work of Dr. Carrel of the Rockefeller Institute in the prolongation of life in animal tissues outside of the body, has recently received confirmation of his work in experiments conducted along the same lines by Professor Harinesco and Dr. Mirea of Bucharest. They reported success in artificially preserving alive cultures of nervous tissue consisting of fragments of ganglia of various mammals which were immersed in the plasma of the animal and at the end of twenty to twenty-seven days began to develop cell structures. It is believed that the Academy will now abandon its previous attitude and accept the statements which aroused so much controversy a few weeks ago.

Babies to Save Rent.—In Paris where workingmen with large families find it difficult to obtain living quarters, a condition to which some at least of the fall in the birth rate has been attributed, an experiment is being tried in the erection of four blocks of flats which will be rented to workingmen at a reasonable yearly sum, with the proviso that the birth of a child will free the tenant from the payment of rent for the following quarter.

In Smallpox Quarantine.—The steamship *Haverford,* which reached Philadelphia on July 8, was detained at Quarantine and her 431 steerage passengers were removed to the Marine Hospital at Lewes, Del., for observation. The last time the *Haverford* docked in Philadelphia the ship's surgeon failed to report that there had been one death from smallpox and several suspicious cases during the voyage, with the result that within three weeks smallpox cases had been reported all through the surrounding country and more than 200 cases were traced to that source of infection. It was therefore decided that on her next arrival the vessel and her passengers would be closely observed.

Homeless Consumptives.—The Tuberculosis Committee of the Charity Organization Society of

New York has gathered statistics for the purpose of showing the need of a reception hospital for the treatment of consumptives in this city. They state that of 29,460 cases of tuberculosis registered in New York, 5,053 were "homeless." Of these, 1,064 were actually without any homes, 2,099 were reported as "not found," and 1,346 lived in lodging houses, and 544 in furnished rooms. The Department of Health is directing its work principally toward reaching those who are in the early stages of the disease, and by continued care preventing its development. This is impossible, however, in the "homeless" cases, and only by providing suitable hospital facilities can the death rate in tuberculosis be largely decreased.

Gifts to Charities.—By the will of the late Mr. George Strauss of New York bequests of $250 each are made to the following institutions: Lebanon Hospital, Mt. Sinai Hospital, Montefiore Home, and Hebrew Infant Asylum.

Red Cross Building.—The Committee on Building and Grounds of the House of Representatives has voted to recommend the appropriation of $400,000 toward the construction in Washington of a building to be used as the permanent headquarters of the American National Red Cross. The building, half of the cost of which is to be raised by public subscription, is to "commemorate the services and sacrifices of the loyal women of the United States during the Civil War."

The Floating Hospital.—On July 5 the Floating Hospital of St. John's Guild, New York, made its first trip down to the Lower Bay, and will continue to make six weekly trips throughout the summer. On July 11, 1,600 mothers with their sick and ailing babies were taken for a day on the water.

New York at the Hygienic Congress.—New York City will have a large exhibit at the Congress of Hygiene to be held in Washington next September, Dr. Schereschewsky, the director of the exhibit, having applied for 500 square feet of floor space and 4,000 square feet of wall space. The exhibit will include a model tuberculosis clinic, a tuberculosis registration office, an infants' milk station, models of the Otisville and other department buildings, and a subexhibit showing the general method of handling and controlling the milk in New York.

An International Extension Course in Psychiatry at Fordham.—In September, 1912, there will be given at Fordham University a three weeks' International Extension Course in nervous and mental diseases. Dr. Jung of Zurich aided by Dr. Smith Ely Jelliffe of New York and Dr. W. A. White of Washington will expound the principles of the Freudian psychology, and Dr. Knauer of the Kraepelin Clinic, Munich, assisted by Dr. J. W. Maloney of New York, will teach the direct experimental method. This course, which in addition to these features will be made up of a complete survey of nervous and mental diseases by eminent European and American specialists, will, it is hoped, prove to be an abiding stimulus to the progress of neurology and psychiatry in America.

Health Activities in Philadelphia.—Plans are under consideration by the Department of Public Works and the Department of Public Health of the city of Philadelphia looking to the inauguration of a campaign aimed at the extermination of mosquitos and rats.

More than 8,450 pounds of fish were recently destroyed on one day by the Chief Meat and Cattle Inspector of the Department of Health. Inspection trips are made daily among wholesale dealers in fish during the heated term.

The 484 steerage passengers arriving from Liverpool on the steamship *Haverford* at the Delaware Breakwater on July 8 were taken to the United States Marine Hospital at Lewes, Del., and vaccinated, and they will be detained for two weeks for observation. The ship and the passengers' effects were disinfected. It is thought that the steamship on its previous passage brought several cases of smallpox into the city.

Obituary Notes.—Dr. Daniel H. Smith of New York a graduate of the College of Physicians and Surgeons, New York, in 1873, a member of the Greater New York and Physicians' Mutual Aid Societies, and for nineteen years a police surgeon of New York City, died at his home, on July 10, aged 60 years.

Dr. Edwin Taylor Davis of Ellington, Conn., a graduate of the University of Vermont College of Medicine, Burlington, in 1888, and a member of the American Medical Association and the Connecticut State and Tolland County Medical Societies, died at his home of pneumonia on June 27, aged 49 years.

Dr. James H. Hutchins of Hampton, Ia., a graduate of Rush Medical College, Chicago, in 1870, and of the New York University Medical College in 1881, a member of the Iowa State and Franklin County Medical Societies, and a veteran of the Civil War, died at his home after a short illness on June 23, aged 6 years.

Dr. Edward Joseph Shanahan of Taunton, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, a member of the American Medical Association and of the Massachusetts State and Bristol County Medical Societies, and formerly city physician of Taunton, died at his home on June 27.

Dr. George W. Henry of Camden, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1885, a member of the New Jersey State and Camden County Medical Societies, and formerly coroner of Camden and a member of the New Jersey State Legislature, died at his home on July 2, aged 53 years.

Dr. William DeKalb Wiley of Richburg, S. C., a graduate of the New York University Medical College in 1888, and a member of the American Medical Association, the South Carolina State and Chester County Medical Societies, and the State Board of Medical Examiners, died at Eureka Springs, Ark., where he had gone for his health, on June 25, aged 46 years.

Dr. David Hudnal Connally of Tyler, Texas, a graduate of the Atlanta Medical College, Ga., in 1860, and city physician of Tyler, died at his home on June 23, aged 74 years.

Dr. John Patten Wales died at Wilmington, Del., on June 27 at the age of 38 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1898. He was a grandson of Major Patten of Revolutionary War fame, and president of the Delaware Society of the Cincinnati. He was at one time mayor of the city of Wilmington. He was a member of his local county Society; of the Delaware State Medical Society and of the American Medical Association.

Dr. Edmund Enquist Hill of Nome, Alaska, a graduate of the Cooper Medical College, San Francisco, in 1895, formerly coroner of San Francisco County, and more recently mayor of Nome, died at his home on June 22, aged 44 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL FÊTE DAY FOR HOSPITALS—3 DAYS DEBATE AT R. S. M.—HEALTH EXHIBITION AND CONFERENCE—PATENT MEDICINES—INSURANCE ACT—OBITUARIES.

London, June 28, 1912.

On Wednesday London presented an unusually festive appearance. It was the day fixed for inaugurating the fête day of Queen Alexander and supporting the hospitals in which she is most interested. The idea had been to carry a rose as a sign of approval and nearly everyone you met displayed the emblem in some form. Ladies of title sold the flowers at every corner or place of vantage. The money thus collected is to go to the hospitals and they are expected to profit by as much as £25,000.

Another way of benefiting hospitals may be mentioned here. It is announced to-day that an anoymous donor has sent £20,000 to St. Thomas' Hospital for the new out-patient department.

The set discussion on syphilis at the R. S. M. extended over three meetings and was concluded on Monday last. Obviously various aspects of the subject were presented, though more or less distributed through the debate. Dr. Norman Moore took up the history of the disease, starting with the publication in 1530 of the poem of Hieronymus Fracastorius, which indicated that it had been recently introduced. Freind's suggestion that it was imported from America by those who accompanied the Columbus expedition though often repeated had no evidence to support it and recently the examination of skeletons from American tombs dating before Columbus shows no evidence, while after that event there is ample proof that the natives suffered severely. Galen's works contain nothing to indicate he had seen locomotor ataxia or G. P. I. and he would not be likely to overlook them. The same may be said of Hippocrates.

Mr. Hutchison suggested that Shakespeare was a victim of the disease, as his writings display intimate knowledge of its symptoms and mental and moral disquietude when he wrote *Timon of Athens*. He suggested that if Shakespeare was the father of Sir Wm. Davenant, as some hold, the portraits of the latter show the physiognomy of congenital syphilis and so supports his suggestion.

Dr. S. Pernet said he had no doubt at all that the Columbus expedition brought the disease from America.

The relation of the disease to the public health was taken up by Dr. Mott, who repudiated the too common belief that it is less prevalent than formerly. It might be assuming latent forms which should be expected in a people syphilized for generations. Latency was more likely when the *locus minoris resistentiæ* was the nervous system, and in this age many neuroses evidently thus originate, including a large proportion of cases of congenital idiocy.

Mr. McDonagh said in no other country was there so great reluctance to discuss this subject and he insisted that instruction should be given about it to soldiers, to school-boys, and to college students. He would even have notification extended to venereal diseases, but in this he was opposed by Dr. Pernet, who objected to placing more power in the hands of the police.

The therapeutic aspect was opened by Mr. D'Arcy Power, who dated modern treatment from 1905, when Schaudinn discovered the spirochete. In 1907 Wassermann published his test. In 1909 Ehrlich issued his "606." Thus it is too early for final conclusions and for years to come results will have to be reconsidered. At first he confessed he was skeptical of the Wassermann test, but he is now satisfied of its great value though it has limitations. We now know that mercury will destroy the causal microorganism in a way that its substitutes or adjuvants cannot. Intramuscular injections of the creams of calomel and metallic mercury as devised by the late Col. Lambkin have given excellent results and were less painful than other formulæ and in no case in Mr. Power's wards were they followed by troublesome symptoms. Of course care was taken to avoid nerves and vessels. It was found better to have the creams dispensed in single doses, in hermetically sealed tubes and to sterilize the syringe by boiling in olive oil immediately before use; the cream and oil mix well, but when water is used for sterilizing bubbles will form. Col. Lambkin's method marked a distinct advance and was followed in detail as to dosage, time of giving, intermitting, etc. Mr. Power regarded the mercury as curative; it was well adapted for army, navy, and hospital practice, but some private patients refused to be injected and then he had recourse to the old perchloride with potassium iodide.

Salvarsan had been largely employed in his wards and he thought highly of it as a remedy for manifestations but had always used it in conjunction with mercury. It arrests the symptoms sooner than mercury and can be used as a test. It must be used methodically, injections once every two or four weeks. Time has to be allowed for the elimination of the large amount of arsenic. The salvarsan was given by intravenous injection, the patient being kept in bed for twelve or fourteen hours previously and every point in the operation was carefully described. As to contraindications some twenty-three fatalities have been recorded, some due to faulty technique, others to the moribund state of the patients or to unfitness for the remedy. The method seemed safe with reasonable caution. Mr. Power concluded with a description of the combined method of treatment from the first stage onwards to the cure, employing the scientific test to determine the intermissions of the mercury from time to time so as to avoid continuing it longer than absolutely necessary. Still he had to admit that Wassermann's test is not absolute, as it remains negative in a certain percentage of cases.

Mr. Ernest Lane agreed that salvarsan was a valuable remedy, though having treated 300 cases its effects seemed less striking than some had alleged. Mercury would cure if given long enough; the two years commonly advised was not enough—he had recommended seven years. Salvarsan must be given with great care to prevent accident. In one case the needle was passed through the distal wall of the vein, resulting in edema of the whole arm for a fortnight. Fatal cases had been recorded. He had treated seventeen cases with neo-salvarsan, which is very soluble in water and causes a slighter reaction, but it caused the symptoms to disappear in the same way as salvarsan. Another preparation—Joha—was introduced as a mode of giving salvarsan intramuscularly and said not to cause necrosis, pain, or toxic symptoms. But one case was in bed three weeks after it with pain in both legs.

Mr. Hutchinson said salvarsan ought to be given

in distilled water. In a fatal case an acid solution was used—much more dangerous than an alkaline. Mercury cured 70 per cent. in two years, according to the Wassermann test. It did not much matter in what form it was given, if the patient were only kept under the influence long enough. Salvarsan acted more speedily, and seeing the possibilities ahead one needed rapidity. Bone pains and cephalalgia disappeared quickly. It was valuable in malignant cases, but disappointed him in deafness and keratitis.

Mr. McDonagh agreed to the necessity of distilled water, but further insisted it should be redistilled immediately before using. He had given neo-salvarsan in 200 cases and preferred it, but its effects should be reinforced by mercury.

Mr. Yearsley found in the deaf schools of the County Council that 39 cases out of 576 cases of acquired deafness were those of congenital syphilis. General treatment seemed useless against that symptom. Repeated blistering seemed of some use.

Mr. C. F. Marshall in a written contribution (read by Mr. Power) expressed satisfaction with the treatment by mercury and potassium iodide, to which well established method he had so far adhered.

The Biennial Health Exhibition and Conference has been held during the last four days. A number of interesting exhibits connected with hygiene were on view, among them quite a collection illustrating the care of infants (the subject of the first day's conference), recumbent invalid lifting methods, useful cheaply made carrying chairs, a model of a shelter for consumptives, etc. The first paper was on "Infant Consultations," and the discussion or conference on this rather equivocal expression was a strong condemnation of artificial feeding. One speaker said a mixed feeding was unmitigated nonsense. Tuberculosis, Dr. Kelynade urged, was best attacked in the child when the chief opportunity of preventive measures was available. So with deafness, which Mr. Yearsley urged was to a large extent preventable. Professor Kenwood had a paper on "Rural Housing," and the health promoting agencies in metropolitan areas were also passed in review. The subjects dealt with yesterday, the concluding conference, included "Need for a Hospital for the Middle Classes at Moderate Fees," and the care and control of the feeble-minded.

The select committee of the House of Commons on the sale and advertisement of patent medicines was occupied during the whole of one day in the examination of Dr. Alfred Cox, secretary of the British Medical Association. He has not held that position very long and may possibly have overlooked some things which have attracted the attention of others. I am certainly surprised at some of his testimony, although as a whole it was correct and straightforward. He said it had been estimated that in 1908 the money spent on advertised remedies amounted to £2,500,000, a sum sufficient to maintain 40,000 hospital or sanatorium beds. He submitted a memorandum on behalf of the association which proposes that the name and quantity of the constituents shall be placed on the label of every packet of proprietary medicines, which shall be also subject to the Food and Drugs Act. Advertisements or labels with false description would be an offense and the Home Secretary would be required to prosecute.

Yesterday Mr. E. F. Harrison, expert analyst, gave evidence as to the composition of these advertised medicines, which ought to be an eye-opener to the public. In one of which was sold at £2 10s, the value of the constituents did not exceed 2 pence halfpenny. Another which would cost perhaps 3 pence to make up was sold at 13 shillings.

The insurance dispute has made no further progress. Other interests besides the doctors are making protests. Last night the Albert Hall was packed with ladies and domestic servants and an overflow meeting had to be held. The strongest expressions were employed and resolutions of resistance carried by acclamation. The Government continues its course. A chief medical officer to the commissioners has been appointed. An independent accountant has undertaken to investigate the conditions and remuneration of practitioners in half a dozen towns. On its completion possibly better terms may be offered. Meantime it is hinted that in default of agreement Mr. Lloyd George will be unmoved and will give to insured persons the money assigned for medical benefits, and let them make their own terms.

Sir John Logan Campbell, M.D., F. R. P. S. Edl., popularly known as the "Father of New Zealand," died at Auckland on June 21 in his ninety-fifth year. He was one of the founders of Auckland, born at Edinburgh, where he graduated, and then entered the E. I. Co.'s service, remaining in it until 1839. In 1840 he went to New Zealand, and in 1855 became superintendent of Auckland Province, and in the next year was a minister without portfolio. He organized the New Zealand Rifle Corps, maintained the Free School of Art at his own expense, was chairman of the Education Board, and a founder of the New Zealand Bank. He was mayor of Auckland the year of the royal visit and presented it with a park. The next year he was knighted.

The death in his eighty-first year of Deputy Surgeon General William Watson, I.M.S., retired, on June 16, recalls the story of his heroic action during the Indian mutiny. In a retreat on account of failure of ammunition a soldier fell wounded in a position where there was no conveyance available. Watson retraced his steps alone, picked up the wounded man and carried him on his back. He received a wound himself on the scalp and suffered from brain fever. On recovering consciousness his first inquiry was for the rescued soldier.

Dr. W. L. Reid, who formerly served in the Light Dragoons, has died at Ealing, aged 91.

OUR LETTER FROM CUBA.

(From Our Regular Correspondent.)

THE BUBONIC PLAGUE—THE NEGRO UPRISING—EFFECT OF ANTITYPHOID INNOCULATION.

HAVANA, July 7, 1912.

SHORTLY following the announcement of the existence of bubonic plague in the neighboring Island of Porto Rico, several suspicious cases have been discovered in this city. On July 6 the National Commission of Infectious Diseases, to which Agramonte and Guiteras belong, diagnosed a case in a Spanish laborer as positive. This is, so far, the only positive case yet found, but there are reasons to think that three previous fatal cases had the same origin. Two of the cases had been diagnosed as pneumonic in type, and another one as septicemic in character. The fact that these patients were of the same social class and that they lived in the near vicinity of the man in whom the plague was diagnosed, as well as the evidence attained by their living in the maritime district, go far to make us sus-

pect the bubonic plague nature of all four cases.

The Health Department has taken strong measures to eradicate all rats and to completely clean up the entire city. Fumigation has been carried on in an extensive area and even the presidential residence and several large newspaper buildings have been included in this measure.

Five cents is paid for each dead rat, and large squads of sanitary employees under the command of Dr. A. G. Dominguez, are employed in order to carry on with great energy the rat destruction. Word has just been received in sanitary circles that Dr. von Esdorf of the Marine Hospital Service and an old friend of Cuba, has been sent by the United States authorities to help us in the fight against bubonic plague.

Yersin's serum has been injected in the case of Mendez Guerra, the Spanish patient now under treatment, and our sanitary authorities, under the command of Dr. Varona Suarez, secretary of health, seem to have the situation well in hand. Reports of the whole island are satisfactory, as no case has been reported from any of the cities and small towns.

Our impression is that the dreaded disease will not gain foothold in Cuba, as a strict quarantine has been established and the prophylactic campaign is being energetically carried out.

The negro revolution which broke out on May 20 in Oriente Province, has been greatly exaggerated. Over 5,000 negroes took to the woods and the Government sent against them about 6,000 regular soldiers and rural guards. Less than twenty of these died as a result of gunshot wounds, the casualties on the negro side being conservatively estimated as over 3,000.

The fact that no cases of typhoid occurred in the army goes well to prove the efficiency of the antityphoid immunizing serum which had been used in a large number of soldiers several months before the revolution broke out.

OUR BERLIN LETTER.

(From our Regular Correspondent.)

THE PROPOSED UNIVERSITY OF FRANKFORT-ON-THE-MAIN—TRUANCY AND NOCTURNAL VAGABONDAGE—CONGRESS ON ORTHOPEDIC SURGERY—POLIOMYELITIS—TENDON TRANSPLANTATION.

BERLIN, April 20, 1912.

THERE has recently arisen in the organization of universities in Germany an idea that is entirely new in German scientific circles. For the first time a city steps forward as the founder of a university. Frankfort-on-the-Main is seeking to accomplish in this line what the State has already done. A large number of scientific institutions and hospitals will be united into one university, which will include the Academy of Social and Industrial Sciences; the city of Frankfort; the Institute of Common Welfare; various foundations, including that established by Speyer; the Senkenberg Society of Naturalists, and various medical institutions. The university will give collegiate as well as postgraduate courses. It is planned that professors in their research work will be unhampered by the needs of administrative supervision and of conducting examinations. There will be five faculties: those of law, medicine, philosophy, natural science, and social and industrial science. The government of the university will consist of two bodies, composed of 32 and 16 members, respectively, and consisting of representatives of the city, of the constituent bodies, and of the various faculties. The consent of the municipal council is the only step that remains before there is established the twenty-second German university.

Truancy and nocturnal vagabondage was the subject of an interesting discourse by Dr. Stier before the Society for the Care of Weakminded Children. Truancy and night wandering are very common in Berlin. The frequent consequences of these practices are in boys criminality and in girls prostitution. The treatment of the evil depends upon the determination of its causes. In the milder cases the cause is the love for adventure; in the more pronounced cases it is an inherited psychopathic constitution. A thorough study of these cases is being conducted in the psychiatric division of the Charitée under the direction of Zichen. Frequently a stay of two or three weeks in the Charitée is sufficient to cure these cases. In other instances special schools, in which the children are given individual attention, are of value. In all cases the children should get sufficient sleep, including rest in bed during the daytime after the school exercises. Bad cases must be sent to correctional institutions.

The season of the big congresses is past. The number of papers keeps on increasing, so that a brief summary of the proceedings is extremely difficult. At the eleventh congress of the German Society of Orthopedic Surgery the subject for discussion was poliomyelitis and the speakers were Krause of Bonn and Lange of Munich. The former had the opportunity of observing the recent epidemic of this disease in the Rhine provinces. The disease broke out during the late summer and early fall among groups of children chiefly from two to three years of age, after an incubation period of from five to ten days. Only 20 per cent. of the cases recovered completely. Among 800 cases there were 150 abortive cases. Professor Lange discussed the orthopedic treatment. In the early stage the enforcement of rest to the paralyzed parts, preferably with the aid of plaster-of-Paris, is indicated. This serves to afford an early relief to the pain. At a later stage electricity, massage, and the application of warmth are indicated. For the prevention of contractures celluloid splints should be used. For the treatment of contractures the measure recommended is tendon-transplantation, which, however, should not be employed in children under four years of age. Of exceptional value is the union in continuity of the transplanted with the paralyzed muscle. Early motion is necessary. Paraffin sublimate silk and oxycyanide silk are efficient in the prevention of stitch abscesses. The knots of the stitches should be flattened out in order to avoid the effects of pressure. The after treatment requires immobilization for six weeks by means of plaster-of-Paris. Tendon-transplantation has produced such good results as to be ranked among the greatest achievements of modern orthopedic surgery.

The Subcutaneous Cellular Tissue in the Defense of the Organism of the Child.—F. Maillot states that the subcutaneous cellular tissue plays an important part in the general nutrition and defense of the organism of the child. This part may be disturbed by hypertrophy or atrophy of its anatomical elements, coupled with obesity, lymphatism, or cachexia. Lymphatism causes localizations of infections; atrophy and cachexia predispose to generalization of the infection and septicemia. Dystrophies of this cellular tissue explain the gravity of infections of cutaneous origin in the child. This shows the necessity of avoiding infections in children especially in the atrophic and cachectic.—*Le Progrès Médical.*

1. Remote Metastases Following Mammary Cancer.—J. C. Hubbard has collected from the literature the reports of 1,952 cases of mammary cancer with a secondary growth in the opposite breast in a little over 9 per cent. of the cases. The thoracic orgens, as one would naturally expect, are frequently involved. In 28 cases occurring in the years 1909 and 1910, there were 22 cases in which the thoracic organs were affected. Of the abdominal organs, the liver is by far the one most frequently involved. The kidney, however, is least frequently involved. The relative frequency of the involvement of the different organs is often quite unreliable when determined clinically. The figures made from autopsy findings should alone be accepted. The following statistics demonstrate this clearly. Campiche, Lazarus, and Barlow collected from 1858 to 1903, 1,110 cases in which no autopsy was made. From these cases there was said to be a metastasis of the liver recognized during life in nine cases, and in the kidney in but one. In a series of 410 cases with a post-mortem examination, the liver was involved in 202 cases, and the kidney in 1—a vastly higher percentage. The same difficulty occurs when one tries to consider the figures of secondary growth in the skeleton. The skeleton is scarcely ever examined unless there are clinical evidences drawing particular attention to a definite bone. In these same 1,110 cases the vertebræ were involved but three times, and the femur was involved but nine times clinically, while in the 470 cases examined with the microscope the vertebræ were involved 32 times and the femur was involved 28 times. Ribbert states that bone metastases in females most commonly follow cancer of the breast, while in the male they are secondary to cancer of the prostate, and the cellular type more often involves the bone secondarily than the scirrhous form. The bone metastasis may be the only one present in the body, the other organs being free. With a bone metastasis, spontaneous fracture is of course liable to occur, and is often the first symptom of any trouble. Metastases of the brain occur in 15 per cent. of all cases.

2. Blood and Stool Examinations in Philippine Scouts.—E. S. Tenney has noted the prevalence of intestinal parasitic infection in a very large percentage of Filipinos, even when living under the favorable conditions of the soldier. The average Filipino can harbor a variety of intestinal parasites without any apparent detriment to his general health. Uncinariasis is common, but seldom causes any definite symptoms. Filariasis is not of frequent occurrence.

3. Causation of Monstrosities.—C. J. Kickham states that the causation of monstrosities by supernatural means (as understood by the ancients) is without foundation. Maternal impressions such as trauma or nervous shock may have much weight. Hybridity need not be considered. Pressure exerted by adhesive bands on the funis, or as the result of trauma, are no doubt the cause of some deformities. Changes in the amnion, no matter what the reason, are acknowledged to be a most certain cause of many types. Some of the minor abnormalities may be the result of disturbances in the fetal period; but the majority of monstrosities can be accounted for only by morbid influences acting on the embryo itself or the germinal cells.

4. Suppurations of the Urethra, Prostate, and Seminal Vesicles.—H. Terry states that pus may mingle with the urine because of urethritis, acute or chronic, due to the gonococcus or other irritant, prostatitis, seminal vesiculitis, stone in the prostatic urethra, neoplasms or ulcers in the urethra; or because of inflammation under a long foreskin. Stone in the prostatic urethra is not common. Inflammations of the prostate and seminal vesicles are the most frequent and important causes of pus in the urine originating in the genital tract. The possibility of tuberculous inflammations of the organs should be thought of.

5. Suppurations of the Urinary Bladder.—H. C. Pitts states that in considering the source of pus found in urine drawn from the bladder, it is necessary to eliminate the kidneys and ureters and the deep urethra. This done one has, first, the bladder wall itself to look to and, second, some pus cavity in the surrounding tissues or in a neighboring organ, emptying into the bladder. Pus from the bladder wall itself is the direct result of an infection, and an infection of the bladder wall is always accompanied by pus. The immediate cause of an infection is the presence of one or more varieties of bacteria; the predisposing cause, an insult to the bladder mucosa. Many infections take place as a direct extension downward from the upper urinary tract, or as an extension upward from the deep urethra. Organisms may be carried to the bladder directly on dirty instruments, or from an infected urethra by instruments, and the instrument that carries the infection may produce the insult that makes its spread possible. Bacteria excreted through the kidneys may find lodgment in the bladder, and again there may be an infection of the bladder by organisms passing through the tissues from the bowel. A hematogenous infection of the bladder is conceivable and probably does occur at times.

8. Operative Treatment of Spina Bifida.—L. G. Paul emphasizes the following points in regard to the treatment of spina bifida: (1) Do not operate if the patient is mentally defective, or if marked paralysis exists. (2) Do not operate on very young babies unless rupture has occurred, or is imminent. (3) Raise the foot of the operating table so that the patient's head will be low, and intracranial pressure maintained. (4) See that the sac is free from nerve elements before ligating the pedicle. (5) A small, temporary drain, down to the lumbar fascia, is advisable.

6. Acute Anterior Poliomyelitis. F. E. Butler.
7. Maternal Nursings. W. M. Hartshorn.
8. Treatment of Chancroids. R. M. Toll.

1. Rotation Treatment of Scaliosis.—A. Mackenzie Forbes presents this as a new method for the treatment of structural scoliosis. Treatment by torsion, according to this method, aims at the unfolding of the deformity with the production of physiological scoliosis on the side reverse to that of the greatest deformity. By means of torsion there may be obtained a correction of the deformity without that lateral pressure which, theoretically, at least, is so greatly to be deplored in the treatment of a compound deformity, of which a crushing, or a narrowing of the thorax is a most important part. The author states that treatment by this method has

been successful. Brilliant results are not claimed, but such cannot be expected in the treatment of an organic deformity which has baffled the wisdom of ages. The application of the first jacket is often followed by an increase in height of one or more inches. On the removal of the first and subsequent jackets, a decided improvement is often noticed. The routine treatment is to change the jacket every six weeks.

2. **Gastric Crises of Tabes.**—J. Friedenwald and T. F. Leitz report their observations in a series of forty-two cases of tabes in which attacks of gastric crises occurred. The patients were all males, whose ages ranged from twenty-nine to sixty-four years. The attacks of gastric crises were noted five times as an initial symptom. Severe pain was noted in eleven cases, was moderate in nine cases, and severe and sometimes moderate, in twenty-two instances. Severe attacks of vomiting were observed in twenty-three instances, moderate in twelve, and severe and again moderate in seven cases. The general health of the patient was affected as a result of the crises in twenty-five instances in the series; the general health was not affected in seventeen. The gastric secretion was examined both during the crises and in the interval. The secretion was obtained during the crises of thirty-five patients; it contained a normal amount of acid in six cases, while hyperchlorhydria existed in thirteen; hypochlorhydria was present in ten, and the gastric secretion was variable in its acidity in six cases. The gastric secretion was secured during the interval of the attacks in thirty-six cases. There was a normal acidity in fourteen instances, hyperchlorhydria in twelve, and hypochlorhydria in ten. If the cases are classified according to the plan of Sainton and Trenc, six cases would fall in the mild variety, that form accompanied by pain, but with little vomiting. Of the abortive variety, there were nine cases of the vomiting form and five of the gastralgic. Of the severe variety there were three cases; this is the form accompanied by extreme pain and collapse. In the complicated variety there was one with hematemesis, and there were four with hypersecretion. In the abnormal variety, that form with very frequent repetition of attacks, there were three cases, and in the variety alternating or associated with the other symptoms, eleven.

3. **Neurasthenia in the United States.**—J. Madison Taylor states that in the United States there is a widespread evidence of constitutional susceptibility to factors of exhaustion. The fundamental agency in the production of nervous irritability, or subversion of vital energies, is to be found in peculiarities of climate not adequately reckoned with, and their corollary, careless omissions to observe economic modes of life, whereby the hurtfulness of local climatic conditions can be escaped. While this holds true for all types of people, it is of special consequence for blonds. Among blonds, especially in the third and fourth generations, are notable instances of neurasthenia to be found in tropical and subtropical countries. Lombroso's tables, showing the monthly genesis of insanity in Europe, bring out the fact that by far the largest number of instances (nearly double) occur from April to August inclusive; least in January and February. Suicide is vastly more common from April to August (most in June and July) with a marked increase on hot days, and especially humid ones. Conscience becomes dulled, loss of temper explosive and extreme, during protracted heat, constituting a gradual debasement by environment. Such effects are especially noticeable in the very young and very old, and more so in women than in men. All these facts are related by numerous and competent observers. If the foregoing postulates can be sustained, then the remedial measures appear to be obvious and urgent. Methods of life should be adopted designed to meet these and similar exigencies. As soon as the summer solstice is established, hours for work should be changed, beginning earlier by an hour, with an extra hour or more at midday devoted to rest—*siesta*. This is especially urgent for those who work in the sun. For all, the hours of work in midsummer ought to be fewer.

5. **Medical Education in Europe and America.**—A. L. Soresi states that in Austria, France, and Germany, education is exclusively a governmental institution. The government pays for the maintenance of every school, including medical colleges. Every position on the teaching staff is open to the widest competition. In every city of a certain size there is a medical college, but only one, no matter how large the population. In Berlin, Paris, and Vienna there is one medical college, representing in this way all that those cities and the government are able to do in the line of medical education. The hospitals belong to the city, and by special agreement with the medical faculties the different professors are enabled to pick up whatever clinical material they require for teaching purposes. Each official professor has special hospital accommodations, by which patients are kept under his care for teaching purposes, and patients are very anxious to be under such care, because they know that they have the very best of treatment and assistance. Every professor is appointed through the widest competition, after having been for some years assistant to some other professor or *privat dozent* or *professeur agrégé*.

8. **Treatment of Chancroids.**—R. M. Toll recommends the following treatment: Wash the ulcer with a 1 to 1,000 bichloride solution and dry thoroughly with a cotton swab. Apply a drop of 4 per cent. cocaine solution. After a minute touch up the raw surface with pure phenol and follow in ten seconds with alcohol. That is all. No powders or dressings of any kind are required. Instruct the patient to return in three days. It is astonishing how much improved the ulcer will be. The raw area will be smaller and shallower and surrounded by sloping, healthy skin—giving it the appearance of a miniature crater at the top of a minature volcano. Repeat the same treatment to the raw surface remaining, and continue so every three days until the ulcer is entirely healed. This will occur after five or six treatments, without leaving a sign of any previous infection.

3. **Prostatectomy.**—G. Kolischer, after referring to the work of Zuckerkandl and Tandler on the anatomy of the prostate gland, says that considering that the hypertrophied part of the prostate is always that which is closest to the bladder, it is obvious that the suprapubic

method ought to be the one chosen. The fact that the "surgical capsule" is composed of compressed and atrophied glandular tissue furnishes a point as to the way access should be gained to the tumor to be enucleated. It emphasizes even more the rule that the covering of the prostate, the vesical mucosa, and the "surgical capsule" should not be perforated by boring with the finger but by incision with the knife. The author is convinced that operating in the dark has something to do with postoperative hemorrhage. The operator deprives himself of the opportunity of seeing and attending to the small spurting arteries. The digging out of the prostate in the dark, with a good deal of force as a rule, may be a source of still more dangerous hemorrhage. The forcible pulling inside the bladder may lead to the detaching of the anterior part of the viscus from its connections and to the rupturing of the big vein located thereabouts. The preservation of the verumontanum and of the ejaculatory ducts which the author claims in his operation can be proven clinically and by ocular evidence. Some patients experience marked increase of sexual power and the author has at his disposal seven urethroscopic findings after suprapubic enucleation in which the verumontanum and the openings of the ducts could be seen through the urethroscope.

4. **Pityriasis Rubra (Hebra).**—H. J. F. Wallhauser reports a case of pityriasis ruba with a discussion of the pathological findings. Hebra emphasized the fatality of the disease though some writers have since mentioned cases that recovered. A thorough microscopic examinnation after death was made in this case. The most important condition calling attention to the grave character of the disease was the degeneration found in the vessel walls. Comparing the general findings and clinical course of the disease, one can assume that the process primarily involved the capillaries, as is evidenced by the early hyperemia gradually involving the vessel walls in an obstructive hyperplasia followed by degeneration; thus accounting for the gradually deepening color of the hyperemia due to the deposit of blood pigment in the corium. The atrophic changes are also accounted for as the result of the hardening of the vessels and consequent malnutrition. The peculiar progressive character of the ulceration was explained as follows: The primary pea-sized ulcer developed as the result of the obliteration of a small arteriole, apparently remaining quiescent until several neighboring branches shared in the process of occlusion, then coalesced and finally extended down through the underlying tissues as the deeper vessels became involved. From the microscopic findings one can assume that in pityriasis ruba one has a condition producing changes in the histological structure of the skin of a permanent character, and until some remedy is found or the etiological factor is isolated and controlled these cases will nearly, if not always, substantiate the prognosis as advanced by Hebra.

5. **Cancerous Degeneration in Chronic Leg Ulcer.**—W. S. Gottheil reports three cases of cancerous degeneration of a chronic leg ulcer. He finds the literature of such cases very scanty though some textbooks mention the subject in a casual way. In spite of the constant irritation and other unfavorable conditions which suggest that cancer might develop from such ulcerations, cancer seems to be one of the rarest of their consequences.

6. **Cowpox Vaccination.**—J. Rosenfeld has found, in confirmation of the results obtained by von Pirquet, that the papilla formation in cowpox vaccination is a local phenomenon. The independent development of each infected point as evidenced by the time of onset, the duration, and other local manifestations bear out this point. It is a local reaction, however, only until the maximum of development is attained. Involution begins simultaneously in all points in whatever stage of local development they may happen to be. Therefore, the involution may be regarded as due to a general reaction or change in the organism. The area formation is undoubtedly a general reaction on the part of the organism. This is clearly protrayed in the simultaneous formation of area in all points in successive vaccinations at the same time with a rise in body temperature and other signs of constitutional disturbances which are in general corresponding in degree to the extent and intensity of the area formation.

7. **Transplantation of Human Cornea.**—A. Magitot states that the proof of the vital condition of the preserved and transplanted cornea lies in the fact that although a pterygium returned after removal it grew only to the edges of the graft, whose tissues must have had sufficient vitality to defend themselves. It must, finally, be noticed that the eye which furnished the graft was in a state of hypertension, the cornea being anesthetized and cloudy. The cloudiness disappeared after being a few hours in the preserving liquid. Eyeballs affected by absolute glaucoma may, therefore, be utilized for this operation. As far as the technique of the operation is concerned, the author still believes that partial keratoplasty is the best method and that it is not necessary to make a large opening in the opaque cornea. No suture is necessary; the operation must be performed at the center of the cornea and one need not have the incisions extend into the conjunctiva.

9. **Reading a Book Page Instantaneously.**—G. M. Gould reports a case of unique vision in which an individual was able to read at one glance the entire page of a book. The ability began to show itself in middle life, becoming more perfect as age advanced. The mental functions were unusually well developed. The man was exceptionally learned, his memory almost faultless. The case is explained by the author as follows: Some time during the middle years of the individual's life the macular region of the retina of the right eye was destroyed by choroiditis due to eyestrain. The fixing part of the retina was obliterated. The left eye was not diseased and continued the perfection of macular or central vision. By long, unconscious and forced exercise the healthy zone of the right retina was educated to such a degree as to be able to receive and transmit to the brain the image of the entire page except that part falling on the destroyed central portion. This was naturally supplied in perfection by the macular region of the left eye. The central visual center thus received the entire photograph of the object seen made complete by the complementing action of the two eyes. It seems impossible to the author that, with retained macular function of both eyes, such a marvelous extension of synchronous peripheral vision could be acquired.

10. **Factors of Safety in Operations for Exophthalmic Goiter.**—C. H. Mayo notes that these operations were formerly attended with a large mortality, but the recognition of these factors of safety is shown today by the lessened mortality of from 1 to 4 per cent. The estimated proportion of cures is about 75 per cent., though some of the symptoms may persist to a minor degree but not enough to affect the working ability or general health. Within the past year the Mayos have operated on a consecutive series of 278 cases without a single death which the author believes is due to taking advantage of the so-called "factors of safety." These are given as follows: (1) As regards operating during periods of exacerbation or excessive activity of the disease; the mortality in these cases is frequently high; one should employ in these cases only the medical treatment, *i.e.* rest, *x*-rays, etc., with attention to the heart, stomach and intestines according to the indications pre-

sented by the individual case, until the exacerbation of symptoms subsides. (2) Gastric crises and acute delirium are serious manifestations and operations should not be done until the conditions have subsided. (3) Dilatation of the heart which exceeds 1 inch is a serious condition, while that of 1½ inches will give a percentage of unavoidable mortality for the radical operation of thyroidectomy. (4) Ligation as a method of surgical treatment has an accredited position in the treatment, and in the early stages patients are sometimes wonderfully improved by simple double ligation. (5) Serious risks are treated by a single ligation of the vessels at the upper left pole. The reaction is about three-quarters as severe as from a double ligation, but the missing one-fourth is an element of safety. If the reaction be very severe a second ligation of the right upper pole is made a week later and the reaction following this is slighter. If it is not severe at this second operation the right lobe, isthmus, and possibly a portion of the left lobe are removed. In some cases of extreme emaciation, yet with a temporary fair or improved condition, a double ligation is made at the one operation. In several hundred patients the average gain of weight after ligation was twenty-two pounds within four months. At this time a thyroidectomy of one-half or three-fourths of the gland can be done with small risk. Ligation of vessels should be made close to or including some of the pole itself to prevent reversal of circulation through anastomoses of the inferior artery. Thyroidectomy of three-fifths or more of the gland is indicated in most chronic cases in which dilatation of the heart does not exceed one inch and in which there are no complications. The small percentage of relapses within one or more years after partial thyroidectomy should have the benefit of further operation. The primary procedure should be ligation of the vessels at the superior pole. If this is not successful a part of the gland can be excised later with but little risk. Ether preceded by atropine and morphine is the anesthetic of choice, but if there is extreme nervousness scopolamine is used, and the worst type of cases with heart and kidney disease are operated on with local anesthesia or have the benefit of Crile's preparation—injecting a local anesthetic into the operative field in addition to the other preparations before ether is given.

11. **Catharsis.**—E. P. Quain states that the function of peristalsis is not limited to the propulsion of intestinal contents but also aids in causing circulatory changes aiding absorption and a more rapid assimilation of absorbed products. Hence, if pathological products exist in the intestines, increased peristalsis may aggravate the symptoms and in acute inflammations within the abdomen, nature's effort is to subdue peristalsis about the infected region. Hence nothing should be done to increase it. The author criticises the common use of salines as tending to destroy the bactericidal properties of the intestinal secretions, and calomel comes under similar condemnation to some extent. When a cathartic is necessary oil is probably the least harmful to the mucosa. All of the author's fatal cases of acute appendicitis, with or without surgical intervention, had, without exception, received and retained some active cathartic at the beginning of the disease, while abdominal inflammations similarly unpromising that recovered had not suffered from the factor of purgation. Patients coming for abdominal operation in emergency without previous preparation suffer less from gas distention than those that have been carefully prepared beforehand, and this is attributed to the use of cathartics in the preliminary treatment.

12. **Intraabdominal Pressure.**—J. Riddle Goffe directs attention to one new feature in the discussion of intraabdominal pressure, namely, that of the reflecting and deflecting planes which determine the direction that shall be taken by the resultant of all the component forces. For many years the author has been teaching the action of the posterior wall of the uterus and the broad ligaments as a deflecting plane of intraabdominal pressure, as it enters the pelvis. The purpose and the physiological function of the many muscular ligaments which the uterus possesses had long been a conundrum, but in the light of their function in regulating the angle of the deflecting plane of the uterus and its broad ligaments, the whole subject becomes clear. The uterus is successively lifted up by the bladder and twisted about on its longitudinal axis by a full sigmoid either to the right or left and, therefore, keeps its ligaments busy maintaining a proper face or plane to intraabdominal pressure which expands itself on this surface, not only in extreme effort, but with the frequency and force of every respiration. In all operations for the restoration of the uterus to its normal position, in cases of displacement, attention must be given at all times to the restoration of this deflecting plane in order to restore physiological function and thereby permanency of result. This is best accomplished by utilizing both the round and the uterosacral ligaments. In the use of the pessary the same principle is involved; the retroversion pessary, in order to be efficient, must reach up sufficiently high above the cervix to take in the slack in the uterosacral ligaments as well as the posterior fornix vaginæ. At the same time, it must not be so long that it cannot yield to intraabdominal pressure sufficiently to permit the uterus to tilt up and deflect the pressure back into the axis of the pelvic outlet. The importance of restoring this physiological deflecting plane of the uterus and broad ligaments is most conspicuous in operations for the relief of procidentia with its accompanying complications of rectocele and cystocele.

Case of Paralysis of the Left Third Cranial Nerve Associated with Left-sided Headache.—D. Hall reports the case of a zinc worker, aged 30; family history good; previous health good; married over three years; one healthy child, aged 2½; one miscarriage one year ago; no history of venereal disease. Present illness: On January 17, 1909, "a pain caught him right across the head." The pain lasted for six weeks and was more severe on the left side. After this gradual paralysis of the left third nerve set in: first diplopia, then complete ptosis; later the ptosis cleared up and the diplopia became troublesome again, and has not left him. He then began to have attacks of left-sided headache with nausea without any of the usual phenomena, and the third nerve paralysis became complete. Present state: The ptosis is now clearing up under mercury and iodine. There are no physical signs of disease other than the left third palsy. Wassermann tests in the blood and cerebrospinal fluid were both negative.—*Proceedings of the Royal Society of Medicine.*

Reactions of the Blood in Carcinoma.—J. A. Shaw-Mackenzie notes that the serum of the blood taken from cases of carcinoma manifests two important properties: (a) an increased antitryptic value; (b) a power to accelerate the action of pancreatic lipase which is far in excess of what is found in normal serum. These two reactions when present together furnish a valuable aid in the diagnosis of malignant disease, and their absence excludes the diagnosis of cancer. After recovery or improvement, or during a period of quiescence, the accelerating power of the serum on lipase remains high, or may be even higher than when the disease is manifest. But under the same conditions the antitryptic value falls to normal. Such reactions serve, therefore, to control treatment and to indicate progress towards recovery or otherwise. The lipoclastic acceleration is a possible and natural factor in resistance to disease, in carcinoma and in other conditions. If this suggestion is admitted, serum and substances which increase this action or protective mechanism are indicated in treatment. Already, although the cases in mice and men are too few to yield decisive results, the author has observed a beneficial influence on malignant disease treated on these lines.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

A PROJECT OF STATE INSURANCE MONOPOLY IN ITALY.

The principle of State Insurance has developed very rapidly since the first modest beginnings were made in the end of the last century. Germany now possesses a most complicated State insurance system, including provisions for indemnifying for injury from accident, disease, etc. The recently proposed scheme in England, with its old age pensions, medical attendance provided by the State, etc., is still the chief topic of political discussion in that country. Much broader, however, than these is the scheme of State insurance embodied in the program of legislation of the present Italian ministry. It proposes nothing more or less than a State monopoly in all kinds of life insurance, thus doing away completely with private enterprise in this branch of commercial activity.

The reasons brought forward by the ministry in favoring the project were as follows: (1) Life insurance business could be carried on by the State without much difficulty. There is no necessity of investing much capital in such industry, no need of expensive plants or machinery, no constant changes in organization. The industry depends most upon the stability of the organization and the confidence of the people in its honesty and good intentions. The ministry claims that in these respects the State surely enjoys marked advantages over any private companies. (2) Competition among private companies is a detriment to the insured. Such competition merely means increase of expenses for advertisement and for agents, and the introduction of various conditions and clauses in the policy merely meant to attract "customers" and not to increase the value of the insurance protection. (3) Life insurance monopoly should prove of great benefit to the government, for it provides a constant source of income, and may thus be used as a means of diminishing other taxes that fall more heavily upon the populace.

The project of the ministry met with much opposition in the Italian House of Representatives. It was pointed out that State agents could not be as effective as agents of private companies in spreading the "gospel of insurance" among the people; that uniformity in policies, which will be almost a necessity under a State monopoly, will not answer the needs of the various classes of population, which are now served by different private companies; that competition among the companies has been of ultimate advantage to the people, reducing rates and developing new and favorable conditions in the policies. Finally, that the State has no moral right to take over a flourishing private industry, just because that industry may help it over its fiscal embarrassment.

These objections have led to a modification of the project, which originally was very radical in form, providing for an immediate transfer of all private insurance business into the hands of the State. The ministry is now willing to allow ten years to the private concerns for winding up their business and also to provide for proper reimbursements of the companies for the loss of their incomes. The project is at present a subject of very lively discussion in the political and business circles of Italy especially as in its changed form it has finally been accepted by both chambers of the Italian Congress. Though in America the agitation for the participation of the State in insurance industry, beyond mere supervision, has not been very strong, the question is of such wide interest that attention of insurance men is called to this new venture in State monopolies. An article by Dr. Rocca in the *Zeitschrift für die gesammte Versicherungs-Wissenschaft* (Vol. XII, No. 3) contains an able discussion of the subject and to it we are indebted for many of the data cited.

What the Life Insurance Companies Can Do to Increase the Physical Welfare of Their Policyholders.—Preventive medicine or measures calculated to prevent disease and preserve health are rapidly rising in public esteem. Of course, it is now well recognized by the medical profession that in preventive rather than in remedial or curative measures the future of medicine lies. This fact is also becoming appreciated by the general public, and Dr. Eugene L. Fisk emphasized this feature of the situation in an address he delivered before the American Association of Life Insurance Examiners at Atlantic City, on June 3, 1912. He is of the opinion that in the direction of health conservation the life insurance companies have a large field in which to work and that their power to prevent much of the needless misery that affects generation after generation of mankind not only affords these companies a magnificent opportunity, but imposes on them a solemn obligation. A start has been made along these lines by the Postal Life Insurance Company, of which Dr. Fisk is medical director. Dr. Burnside Foster of St. Paul suggested some three years ago that the periodic medical examination of policyholders would be a step in the right direction and this suggestion modified to the extent of granting examinations annually instead of quinquennially was adopted and incorporated into the Health Bureau scheme of the Postal Insurance Company. Health conservation in some form is now practised by five out of 231 old-line companies and, of course, the Health Bureau established in the Association of Life Insurance Presidents, in 1910, is doing valuable work, but, as Fisk points out, that bureau is engaged chiefly in accumulating information regarding health legislation, health conditions in certain localities, etc., and the operations are necessarily restricted. It exerts no systematic, direct influence upon policyholders. Moreover, it is hampered in the scope of its activities by lack of funds, as a yearly appropriation of $5,000 cannot go very far in the protection of 20,000,000 people.

Fisk rightly insists that the work of conservation of health by the insurance companies must be definite and practical, and in offering a scientific and practical reason for health conservation in life insurance, he believes that the following questions must be answered: 1. Is the present death-rate among insured lives necessarily a fixed quantity? 2. If not, how can the death-rate among insured lives be lowered? 3. What will it cost? 4. What will be the saving in dollars and cents? 5. What will be the influence upon life-insurance medicine? 6. What public service will be rendered? As for the first question, although some people doubt whether the present very favorable rate of mortality among insured lives can be lowered, Fisk holds the view that the mortality in the average well-managed company is far higher than it need be, and he illustrates this by a chart, derived from the experience of the United Kingdom Temperance and General Provident Institution of London, in which it is

demonstrated that abstainers show a much lower mortality rate than moderate drinkers. Other companies record like results. Therefore, Fisk argues that if one hygienic factor alone can lower the mortality in a large body of insured lives, then we are forced to the conclusion that the death-rate in the general section of these companies and in all other companies in which there is an exposure of average risks, is not a necessity, but could be materially lowered by superior living-habits. With regard to question 2, over and above the periodic examination of policyholders already referred to the author chiefly pins his faith on the education of the public in matters hygienic.

The cost would be heavy. In five leading companies, with about 2,230,000 policyholders, the cost of an educational campaign would be about $150,000 annually. The cost of periodic medical examinations would be a much more serious matter. However, the ordinary examination, urinary analyses being made at the home office, can be procured at $2.00 each. Physicians who are members of societies that will not permit them to make examinations for insurance for less than $5.00 are perfectly willing to make these Health Bureau examinations for $2.00, as they do not present the peculiar difficulties that are involved in an examination for new insurance. It must be clearly understood that the object of the system is not alone to detect disease in time to check or cure it, but to encourage a closer relationship between policyholders and the medical profession, thus shielding them from the pernicious influence of quacks, charlatans, neighbors, patent-medicine vendors, and temporizing home treatment. The results of these examinations are, as a rule, made known to the family physician, with the consent of the policyholder. Probably not more than ten per cent. of the policyholders would avail themselves of the privilege, at least for a number of years, although many would be influenced to undergo regular medical examination by their own physicians. The aggregate cost of periodic medical examinations in five companies with a total of 2,230,000 policyholders would be about $520,000 annually, assuming that only 10 per cent. availed themselves of the examinations. The total annual cost, therefore, of a comprehensive system of conservation in such a group of companies would be about $670,000. The saving through conservation would be to some extent problematical, although Fisk adduces some interesting computations. By efficient conservation work a company may reasonably expect to reduce the mortality on 10 per cent. of the risks to the rate experienced by the abstainers. Now, the net premium or actual cost of insurance for the non-abstainers, assuming that 75 per cent. of the risks were insured under the whole life policies and 25 per cent. under endowments, would be $25.98 at the age of 35, while the net premium for the abstainers would be $22.95, a difference of $3.03 in favor of the abstainers. Applying this factor to the insurance at risk in five leading companies during 1910, which amounted to $5,588,794,093, and the results, assuming that 10 per cent. of the business was favorably influenced by health-conservation, would be as follows: Mortality savings from conservation $1,692,496, deducting cost of Educational Health Bureau will leave $1,542,496, deducting cost of examining 10 per cent. of policyholders $520,000, will leave a net saving of $1,022,496. Fisk thinks that the ultimate meaning to the medical profession and to society will be for the good of both. As regards the medical profession, a comprehensive system of prevention of disease will reduce the need for treatment and this will curtail the revenues derived by physicians from diseased individuals. However, that is the highest aim of scientific medicine to-day which absolutely disregards the unfavorable financial reaction upon the profession from such endeavors. The author holds that the attitude of scientific medicine may well put to scorn those who cry, "A medical trust," while deriving their own revenue from the credulity of the sick and suffering. Let the people who are back of this cry do something to prevent disease and reduce their revenues from the afflicted and they will avoid the countercharge of constituting "a misery trust." The public service rendered will be the dissipation of ignorance. An educational campaign which persistently and systematically reaches directly or indirectly, perhaps, 60,000,000 people, will do much toward dispelling the gross superstition and ignorance that is still so widespread, regarding matters of bodily health. By demonstrating that those who neglect or abuse their bodies are not only poor animals, but bad business assets, that communities without efficient and sufficient health protection are likewise bad national assets and a drag upon the country's progress, there will result a more positive response to the efforts of agencies for social reform and uplift, and health conservation in life insurance will become a powerful civilizing force.

Relations of Lesions of the Liver and Gall-Bladder to Life Insurance.—C. W. Pierce says that a large number of policyholders die each year from diseases of the liver or gall-bladder, males developing cirrhosis, and females gallstones, cholecystitis, and cancer. He thinks that tight lacing is in women one of the causative factors of liver disease, because of production of "corset liver." Quincke thinks that gallstones, gallstone colic, inflammation of the gall-bladder, cancer, perihepatitis may be frequently due to this condition. Moreover, tight lacing and even tight clothing outside of corsets may cause disturbances in other organs, favoring the production of movable kidney on the right side, ptosis of the stomach, stasis in the portal circulation, intestinal catarrh, hemorrhoids, constipation because of this stasis. Stasis of bile predisposes to the formation of gallstones and such stasis takes place in women with "corset livers," the frequency of which in autopsies has been shown to exceed 25 per cent. Pregnancy and abdominal tumors are the two other predisposing factors in the development of gallstones in women. Cancer and gallstones are very frequently present together in women, the irritation of the stones predisposing to carcinoma of the gall-bladder. Courvoisier found this coexistence of stones and cancer in 90 per cent. of cases.

About one-third of all cases of hepatic cirrhosis are due to immoderate use of alcohol and three cases of this disease are found in men to one in women. Of course, individual resistance to alcohol plays a very important rôle in deciding the character of the effect it may produce. Examiners should accordingly be on the lookout for such conditions of the gall-bladder or of the liver. Moreover, as practitioners they should teach prophylaxis by advising against tight lacing in women and excess in alcoholic beverages in men. Pierce thinks that policyholders should be reexamined at stated intervals and such as are degenerating because of drink should be eliminated.—*Southern California Practitioner*, May, 1912.

Book Reviews.

Some Recently Discovered Letters of William Harvey, with Other Miscellanea. By S. Weir Mitchell, M.D., LL.D., F.R.S. With a Bibliography of Harvey's Works by Charles Perry Fisher, Librarian of the College. Transactions of the College of Physicians of Philadelphia, 1912.

This is a small volume, but it is one of great interest. Dr. Weir Mitchell here gives us some of Harvey's letters which have only recently been discovered, and which, but for this charming brochure, some of us might never have an opportunity of reading. To every one interested in the history of medicine and science, and particularly in the details of the life of the great physiologist this pamphlet will be found entertaining and instructive. The book includes a useful bibliography of Harvey's works compiled by the well-known librarian of the College of Physicians of Philadelphia. The pamphlet concludes with an estimate of Harvey's character, from which we quote two sentences: "Concerning scientific differences and hostile comment on his discovery, he was charitable, magnanimous, and well-mannered in his replies, a model for those men of science who bitterly resent opinions contrary to their own." . . . "That he was a reverently religious man is written in many a page of his works—surely, taking him for all in all, a model of what is best in the physician and the gentleman."

Studies in Psychiatry. Vol. I. By Members of the New York Psychiatrical Society. Price $2.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

This volume is the ninth of the series of monographs on nervous and mental disease, edited by Smith Ely Jelliffe and Wm. A. White. Several articles of the fifteen making up its table of contents have interest for the specialist alone; many others, however, should claim general attention. Of the latter, the following may be named: The Curability of Early Paresis, by Dr. Charles L. Dana; the Diagnosis of General Paresis, by C. Macfie Campbell, who gives a résumé of histories and pathological findings in several illustrative cases: Clinical Varieties of Periodic Drinking, by Dr. Pearce Bailey; A Study in Race Psychopathology, by Dr. George H. Kirby; Ocular Reactions Among the Insane by Drs. Diefendorf and Dodge, etc., etc.

The papers are well and entertainingly written and are more ambitious than those usually heard in society meetings. It is therefore quite proper that they should appear in their present permanent form. We recommend the monographs of which this is one to the attention of physicians; their acquisition should form quite a nucleus of a library of modern thought in the study of nervous and mental disease.

The Friends of the Insane. The Soul of Medical Education, and Other Essays. By Bayard Holmes, M.D., Chicago. Cincinnati: The Lancet-Clinic Publishing Company, 1911.

Dr. Holmes has a mission, and that mission consists in telling the medical fraternity about the shortcomings and even the crimes in the modern treatment of the insane. He thinks that the insane are looked upon too much as a source of danger to the community, and too little as patients whose disease should be scientifically studied. In other words, research of insanity has been subordinated to mere restraint of the insane, and thus prevention and cure of insanity become impossible because of the lack of knowledge of its etiology.

Dr. Holmes wields a ready and a sharp pen, and these short essays of his are recommended to those, whether lay or professional, who are interested in the subject.

Differential Diagnosis. Presented Through an Analysis of 385 Cases. By Richard C. Cabot, M.D., Assistant Professor of Clinical Medicine, Harvard University Medical School, Boston. Second Edition, Revised. Profusely Illustrated. Price $5.50. Philadelphia and London: W. B. Saunders Company, 1912.

In this book Dr. Cabot takes the reader into his confidence, so to say, and tells him the course of his thoughts when at the bedside of a patient. That patient is made an actuality to the reader, as he was an actuality to Dr. Cabot, by the recital of the history, the physical findings and such other matters as would clear up the situation. These data set up a certain train of thought in the reader, which he can then compare with the train of thought that has passed through Dr. Cabot's mind, and is put down by him in the discussion of the differential diagnosis. The author, then, acts as a consultant, pointing out what facts should have been learned in each case and what logical inferences can be made from them. The various cases are grounded according to the "presenting symptom" or chief complaint heard from the patient, such as headache, lumbar pain, general abdominal pain, epigastric pain, etc., etc. Each chapter is introduced by a discussion of these symptoms, and a statistical study of them.

The book is not only a most practical guide for a practitioner, giving him the opportunity of learning from the actual cases seen by such a busy consultant as Dr. Cabot, but is also extremely stimulating, this quality being derived as much from the originality of its method as from the frequent quaintness and charm and the constant honesty of Dr. Cabot's discussions.

We do not recommend the book to students; it is not a textbook and many cases of diseases discussed are either too rare or too atypical to be profitable for the undergraduate. On the other hand, we know of no better book for the practicing physician, and especially for the man who is just through his hospital course and is entering practice. To them Dr. Cabot's book should prove invaluable.

Sex Hygiene for the Male and What to say to the Boy. By G. Frank Lydston, M.D., Professor of the Surgical Diseases of the Genitourinary Organs and Syphilology, Medical Department State University of Illinois; Member of the American Medical Association; Member of the American Urological Association; Member of the Society of Authors of London, England; Author of Diseases of Society, the Blood of the Fathers, Etc.; Delegate from the U. S. Government to the Congress for the Prevention of Infectious Diseases, Brussels, Belgium, etc., etc. Price $2.25. Illustrated with 24 Engravings. Chicago; The Riverton Press, 1912.

This volume is aimed to fill the demand for a book that would serve as a popular treatise on sexual hygiene. This is a subject the importance of which has gained universal recognition within recent years, particularly among sanitarians and educators. The book is designed for pupils of the high school age and older, for their parents, and for their teachers. The scope of its subject matter may be adequately indicated by an enumeration of some of the topics discussed as follows: the lie of the wild oats; the social evil; physical training; methods of muscle building, forms of athletics, bathing, and massage; general principles of sexual hygiene and maintenance of health; suggestive literature; suggestive theatricals; marriage; nonvenereal diseases; diseases of the procreative function; the venereal diseases, and a word to teachers and parents and what to say to the boy. The book is written in plain, unequivocal, and elegant language, by one who has authority to speak on this subject to the youth of the land.

Milk and the Public Health. By William G. Savage, B.Sc., M.D. (Lond.), D.P.H., County Medical Officer of Health, Somerset; Late Medical Officer of Health and Public Analyst, Colchester; Lecturer in Bacteriology, University College, Cardiff; Assistant in Charge of the Bacteriological Department, University College, London. Price, $3.25. London: Macmillan & Co., Limited, 1912.

The increasing recognition of the importance of municipal regulation and supervision of the milk supply, imparts particular value to an authoritative treatise that deals with the many phases of this vast subject. The present volume admirably fills the demand for such a work. Its subject matter is presented in three parts: Part I takes up the bacteriology of milk and the relation of milk to human diseases; Part II deals with the bacteriological examination of milk; Part III discusses the public health control of the milk supply. The first part presents an exhaustive summary of the scientific knowledge with reference to milk and its relationship to disease. The second part is matter for the laboratory worker and the third part deals with the administrative aspect of the subject, describing the existing conditions of the milk supply, the reforms in these conditions; the legal powers in England applicable to milk, the prevention of human tuberculosis of bovine origin; the special methods to obtain a pure milk supply, artificial methods for the preservation of milk, and machinery and procedures to obtain a pure milk supply. There are also appended the Manchester tuberculosis milk clauses, the tuberculosis order (1909) of the Board of Agriculture, the Danish (1904) tuberculosis act, the milk and dairy bill of Mr. John Burns, the New Jersey Certified Milk Act of 1909, and the reports required and rules enforced by an English Milk Company.

Society Reports.

NEW YORK PSYCHIATRIC SOCIETY.

Stated Meeting, Held March 6, 1912.

CHARLES L. DANA, M.D., PRESIDENT, IN THE CHAIR.

Bleuler's Schizophrenia.—Dr. AUGUST HOCH read a review of this subject, in which he said Bleuler was of the opinion that dementia præcox constituted a very large group of cases or a set of groups. According to him it comprised much more than was ordinarily included. In spite of suggesting the possibility of subgroups, he looked upon the disease as due to a definite disease process, probably an intoxication which he admitted we do not as yet know but which produced certain fundamental symptoms, notably a disorder of the associations consisting in a general loosening of their affinity, and certain physical symptoms. It was a disease which varied much in course and in outcome, though every case showed some defect after the acute symptoms had disappeared. Latent cases also occurred, that is, conditions which did not lead to commitment and which showed no active symptoms. The marked symptoms or syndromes, however, were not the direct outcome of the disease process, but were due to the influence of emotions exerted through mechanisms which Freud had taught us and which could not be understood without a thorough appreciation of the unconscious mentation—studied therefore by means of psychoanalysis. These mechanisms produced in dementia præcox such marked and lasting influences because the fundamental association disorder furnished a basis upon which this was possible. Therefore a great deal of the symptom picture in dementia præcox was explained on the ground of psychogenesis. Owing to the many objections which had been raised against the term dementia præcox, Bleuler introduced the term schizophrenia instead, the most marked characteristic of the symptom picture being dissociation, produced on the one hand by the fundamental disorder, and on the other hand through Freudian mechanisms. In criticism Hoch said that while Bleuler's book contained an excellent description of symptoms and the most valuable and fruitful suggestions, it seemed difficult to prove the existence of the fundamental association disorder because psychogenic mechanisms produced the same results. Psychogenesis, therefore, seemed applicable in a wider sense than Bleuler was willing to admit. This was, however, only possible if we accepted the existence of congenital tendencies to abnormal makup, which allowed the psychogenic mechanisms to become fixed and to show themselves in special ways. But of course if dementia præcox was essentially a disorder of instincts, there must be a physical side to the disease, be it in the form of abnormal internal secretions or other metabolism disorders, or what not. But this physical side evidently stood in a different relation to the abnormal functions than was the case in general paralysis, for example. When we spoke of psychogenesis, we did not mean to exclude this physical side, but since we knew so little about it and since we could describe a good deal in the clinical picture and development of dementia præcox psychologically, we preferred for the present to deal with that which we knew and which we could express in mental terms. Finally it must be stated that in the realm of the more functional psychoses, viz., dementia præcox, manic-depressive insanity, paranoia, the psychoses of degenerates, etc., we were dealing with disorders which grew out of the personality, which were therefore not apt to be circumscribed diseases as were the organic disorders, but must be looked upon as mental reactions, between which transitions occurred. For this reason a one-word diagnosis often expressed inadequately the real situation. It was from this point of view that a widening of the conception of dementia præcox was not indicated.

Dr. A. ROSS DIEFENDORF said he was interested in Dr. Hoch's criticism of Bleuler's contribution to the psychogenesis of dementia præcox. Dementia præcox had become a very large group statistically, so that it now included practically everything outside of the organic psychoses and typical cases of manic-depressive insanity. That being true, the speaker thought Bleuler's comprehensive grouping indicated a step backward.

Dr. STEWART PATON wshed to refer to one point in connection with the psychogenesis of symptoms. Clinicians were apt to forget how complicated were the phenomena of consciousness. The study of comparative physiology emphasized this complexity. Consciousness was not, as some clinicians affirmed, an isolated phenomenon. There was clearly a great field in psychoanalysis, and the possibilities were clearly outlined in Dr. Hoch's paper.

Dr. GEORGE H. KIRBY said Bleuler's work interested him particularly because of the excellent analysis of clinical symptoms which the author gave. The arguments which were brought forward to support the hypothesis that in these cases we were dealing with a special disease process, were, however, far from convincing. Bleuler had picked out a few symptoms which he considered to be fundamental, but which after all were extremely widespread, shading off on the one hand into simple constitutional abnormality, and on the other hand, according to the author, appearing in the well circumscribed toxic and organic conditions, such as the alcoholic psychoses and general paralysis. Such a conception certainly tended to obscure many important issues and instead of helping us to narrow down the dementia præcox group, or at least to make various smaller subgroups, the whole problem became at once tremendously diffuse, and dementia præcox would comprise an even more unwieldly and heterogeneous mass of cases than ever before.

Dr. L. PIERCE CLARK said that while Bleuler's conception was a masterly presentation of the functional psychoses by and large, it seemed to give us no special help in understanding and dealing with specific cases or groups of cases, the essential need of the present state of the subject. It was interesting to see that Bleuler would make schizophrenia embrace not only the crazy episodes of the precocious dement, but the entire defects of makeup of the case from birth as well. Although this position might be the true psychobiological one for these mental disorders, it furnished little that was essentially new. Dr. Hoch's excellent critical review of the work in itself was a distinct and unique contribution to our knowledge of the functional psychoses and neuroses.

Dr. FREDERICK PETERSON had found this description of Bleuler's work very interesting. He had great respect and admiration for Bleuler because he was an especially clear and original thinker, but he did not think we should enlarge the scope of dementia præcox too much, otherwise dementia præcox would become synonymous with insanity.

Dr. SWEPSON J. BROOKS said we had all suffered from too large a classification and the desire to label our cases in accordance therewith. The more one delved into that sort of thing, the more it seemed to show that most of the psychoses depended upon the fundamental defect which Bleuler seemed to have found in so many of the cases examined and analyzed by him.

Dr. C. MACFIE CAMPBELL said Bleuler had made a valuable contribution to the analysis of a large percentage of cases of mental disorders, but the very largeness of the percentage indicated a certain weakness in his method. It showed that the psychopathological principles with which he dealt were of wide validity, but at the same time were too wide to be used as a sufficiently discriminating basis of classification. The stress laid on the mechanisms had led to the comparative neglect of wider considerations as to general symptomatology and course. As the mechanisms referred to were also met with in other disorders as well as in normal life, it was not surprising to find that there are all transitions from a marked schizophrenia through latent forms to practically normal individuals. With such a conception the introduction of a hypothetical morbid process would strike one as rather artificial. Bleuler would lead us from Kraepelin's dogmatic dementia præcox to another equally dogmatic presentation with a still stranger name.

Dr. HOCH, in closing, said the book of Bleuler was one which every one who worked in psychiatry must read, because it was of the greatest importance, and from what had just been said the other members of the society seemed to agree essentially with what he had expressed. He perhaps had not made it sufficiently clear that in our studies of psychiatry we were not so much concerned with classification as with the sizing of the different factors which entered into the clinical picture. In regard to Dr. Paton's remarks he would simply state that he was well aware that a great deal entered into mental phenomena which could not be expressed in mental terms, but this should not detract from an attempt at present to describe as much as we could, in the sequence of events, psychologically.

The Mental Hygiene Movement.—Dr. WILLIAM L. RUSSELL of White Plains, N. Y., read this paper. (See page 111.

The President, Dr. CHARLES L. DANA, said that it seemed to him the Psychiatric Society was to some extent under obligation to consider this problem, and perhaps take some action in regard to it as well as discuss it. He

hoped in the discussion the question as to what we might do would be brought up.

Dr. KNAPP said that, while a movement of this sort if kept strictly under intelligent control might be capable of considerable assistance, it might also be attended with very serious danger. The "social service" movement, for example, was at times useful, but the "social worker" might often become so imbued with the sense of her omniscience that she would assume the authority of the physician, as in a case recently reported to the speaker in which a "social worker" set aside the recommendations of a neurologist and urged the patient to go to the Emmanuel healers. Any question having to do with mental disease and its treatment had a certain attraction for a large number of psychopathic, unbalanced individuals, who, if they could obtain control of some organization, might cause very great harm. Although the intelligent cooperation and assistance of the general public was desirable, our first aim should be to instil a little psychiatrical knowledge into the minds of the medical profession. He had just discharged from his service a patient with the gastric crises of tabes—a typical case with absent kneejerks, Argyll-Robertson pupils, etc. Three surgeons in three different hospitals had opened this man's abdomen and found nothing. The ignorance of the profession, great as it was in regard to nervous diseases, was even greater in regard to mental diseases. If the profession could be enlightened it would be vastly more helpful than to encourage the cooperation of the laity.

Dr. HENRY A. COTTON said he had been very much interested in hearing of the work of the National Committee, and was inclined to think good results would come from the work as planned by them. It was a significant fact, as explained by Dr. Russell, that the fund had been given for the express purpose of investigating the present condition of the insane. All knew that the care and treatment of the insane was not uniform throughout the country, or even in some cases throughout the hospitals in one State. Some States had made progress while other States were caring for their insane patients in much the same way as they did twenty-five years ago. The speaker did not want to be put in the position of criticising other institutions, realizing that he had plenty of serious faults in his own hospital. But he thought the work of the National Committee could be carried on in a quiet manner, without undue publicity and without criticising unjustly, and so produce excellent results. In a recent discussion with several institutional men the question was brought up whether it would not be a good policy to score the various State institutions according to their merits. Undoubtedly there should be some method of comparison. There should be some standard and an effort made to bring up all hospitals as far as possible toward this standard. There should be judicious inquiries into the conditions of the various hospitals, not for the fact of publicity, but to find out the real state of affairs. The Board of Managers of the insane hospitals, as a rule, entirely ignorant of what was being done in other hospitals throughout the country, frequently were ignorant of the progress that was being made, not only in the care and treatment of the insane, but in work along scientific lines. In many cases superintendents were anxious to inaugurate modern methods and to install new apparatus but were unable to do so because of the question of expense. If, on the other hand, lack of development and lack of progress were due to the superintendents, the committee would act as an efficient aid to spur them on to more activities along modern lines. There was no doubt that great progress had been made in our State hospitals, and the speaker appreciated the good work which had been done in New York and other States in the East, as well as in some of the Western States, but he thought all would agree that there was very much more to be done before we could say that there was any uniformity in the work of the hospitals.

Dr. CARLOS F. MACDONALD said the subject was one of great importance, but there might well be a difference of opinion as to the best method of carrying out the proposed reform. It seemed to him it involved a work that should be largely done, or at least participated in, by the laity, especially those who were interested or engaged in philanthropic work, aided and assisted by the general practitioner, the family physician. In other words, the public and the general profession should be supplied with a practical knowledge of the causes, the nature, and the forms of insanity, and particularly as to its early manifestations, to the end that they might be able to recognize its onset, in order that means might be taken for its arrest before the disease had become fully established. This suggested the field of operation for the alienist and the one in which he could best promote the propaganda, namely, by leading the general practitioner into the realm of psychiatry. But in order to do this successfully the subject would have to be simplified far more than it was to-day. He agreed with Dr. Knapp in what he had said relative to the importance of diffusing among the general profession a working knowledge of mental diseases. Even under the old classifications and terms the general practitioner was prone to stand aloof from the study of psychiatry and to regard the subject as something beyond his ken, to which the alienists alone possessed the key. But, under the new dispensation, with its new nomenclature, its new theories, and its involved, complicated, and tedious methods of case-taking, the subject was rendered still more mysterious and difficult of comprehension to the busy general practitioner. Every physician in general practice should possess a knowledge of insanity sufficient to enable him to recognize cases when he met them, to determine the form of the disease, and to care for them properly until such time as they might be committed or otherwise disposed of. The speaker could not subscribe to the suggestion that in our present methods of caring for the insane we were proceeding along substantially the same lines that were in vogue forty years ago. During the more than forty years that he had been engaged in the care and treatment of the insane and the management of the institutions therefor he had witnessed very marked improvement, both in the methods and in the provisions for the care of this class of diseases, improvements that had generally been adopted and put into operation throughout the entire civilized world. So that the modern hospital for the insane of to-day represented everything that medical science had suggested, whether for the cure of the curable or the amelioration of the incurable. And yet, despite all that had been done, it was a lamentable fact that the recovery rate had not appreciably increased. This movement, as outlined by Dr. Russell, was certainly a most worthy one and one which called for the best effort of every alienist, individually and collectively, for the prevention of insanity.

The President, Dr. DANA, said the main question was whether the society should take some action in connection with this movement; whether the members should put themselves on record as offering their cooperation.

Dr. HOCH said, in regard to Dr. Dana's proposition, that it seemed eminently fitting that this Society should give its cooperation to this movement. It had been a very difficult task to formulate the plans for the National Society, and the whole question of prevention of insanity, in which such factors as the medical education, school hygiene, the spreading of knowledge in regard to the causes of mental disease, and greater attention to the mental development in childhood and infancy must be taken into consideration, was particularly difficult to formulate. But there was no other way to begin than to launch this movement somehow, and it seemed to the speaker rather wise that the National Committee should start with a survey of the present treatment of the insane.

Dr. DANA asked whether it would not be well to keep track of the movements of this committee and act as a conservative factor. He had heard many express the opinion that if this committee was going to work to investigate medical colleges they were opposed to it; if it would be antagonistic to many alienists and Boards of managers it would not be a wise movement. We did not want to do that.

Dr. A. ROSS DIEFENDORF, speaking for the work in Connecticut, said he had been in touch with it there since its inception, and could report a healthy growth. The duties of the "social worker" were increasing monthly. This included the investigation of special and needy cases, after-care work, and visits to a dozen or more institutions. There were many visitors and inquiries from all parts of the State asking for a variety of information. Indeed, it was evident that the society had established for itself a definite place in the care of the insane in Connecticut.

Dr. WILLIAM L. RUSSELL said Dr. Salmon had had considerable experience. He was two years at one of our State hospitals and for several years was employed on Ellis Island examining immigrants in regard to their mental state. He organized there a small hospital for cases under detention. He had also done some statistical work for the State Commission in Lunacy and had been chairman of the Bureau of Alienists concerned with the deportation of the alien insane. He had, in fact, devoted a lot of time to mental diseases for a number of years. He would like to say that one remark in his paper was that the plan was not with a view to making statistics for to publicity, though what he had stated was not to be looked upon as an authorized statement for the committee. It was based on his own information as far as it went. The

object of making an investigation in several States was to bring about some organized effort for the improvement of conditions in these States. While the speaker was willing to accept all criticisms that had been made and realized the dangers fully, he did think there was something more to be done in bringing about better conditions in the care of the insane than simply educating the medical profession, although he thought that was the most important thing that could be done. If a promising movement was started to bring this about he would leave the present movement and go into that. The questions at issue involved, however, other than purely medical considerations. Legislative and administrative methods went far in accomplishing results that were effective, and in that he thought the laity must have a hand. The people paid the bills. In any case this movement was not one that was waiting for the medical profession to start; it had been started already, and to a considerable extent had been started by laymen. If we had any duty in the matter, and Dr. Russell thought we had, we should try to support it and guide it along rational and proper lines.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF FLORIDA.

Jacksonville, May 6 and 7, 1912.

ANATOMY.

1. Locate the fascia lata.
2. Name the bones of the wrist.
3. Name the bones of the larynx.
4. Describe the portal circulation.
5. Describe the chambers of the eye.
6. Name all the organs in the peritoneal cavity.
7. Define articulation; symphysis synchondrosis.
8. Name and locate the ductless glands of the body.
9. What is the prostate gland, Cowper's gland, Bartholin's gland, carunculæ myrtiformes?
10. What structures would be divided in a cross section of the body at the seventh cervical vertebra? At the sacro-coccygeal juncture?

PHYSIOLOGY.

1. What is the difference between anabolic metabolism and catabolic metabolism?
2. What are fats and how are they digested and carried into the circulation of the blood?
3. What are the chief constituents of normal fresh urine?
4. Describe the locations at which the different sounds of the heart can be heard the plainest, and what produces each sound.
5. What is meant by normal blood pressure and how is it ascertained?
6. Why does the normal temperature of the body remain the same in hot weather as it does in cold weather?
7. What are the functions of the liver?
8. What are proteins, and which of the digestive ferments act upon them?
9. Describe respiration and what keeps it going?
10. What are leucocytes; their composition, and describe their functions and actions in the living body?

CHEMISTRY.

1. What use is made of the syllables *ous* and *ic, ite* and *ate* in distinguishing compounds from each other?
2. Express the chemical equation resulting from a mixture, in solution, of sodium carbonate and calcium chloride.
3. Describe the flame test for potassium, sodium, and cuprum (except cupric and cuprous compounds).
4. Give treatment, in detail, for acute carbolic acid poisoning.
5. Describe symptoms of acute belladonna poisoning, and give treatment.
6. Describe symptoms of acute cocaine poisoning, and give treatment.
7. Describe chyluria and how recognized.
8. Describe the metallic copper test for arsenic.
9. What are the physical properties of phosphorus?

MATERIA MEDICA AND THERAPEUTICS.

1. Mention three classes of evils which may result from chemical incompatibilities in prescriptions. Write such a prescription.
2. How does cold reduce temperature, and how best applied?
3. Name four classes of medicines, with an example of each class, and give dose of example.
4. Name five antiseptics and tell in what proportion each should be diluted for surgical purposes.
5. Name the mineral tonics. Write a prescription containing the most useful.
6. An anesthetic being indicated, state the conditions that render ether preferable and those that render chloroform preferable.
7. Mention some of the indications and contraindications in your use of ergot.
8. Where is the habitat and what are the physiological effects of digitalis?
9. Name three drugs used in the treatment of malarial fever. State how each controls this disease.
10. Give the theory of the alkaloid treatment of rheumatism.

OBSTETRICS.

1. Give diagnosis of pregnancy.
2. Describe the fetal circulation.
3. Describe pelvimetry and give the normal pelvic measurements.
4. How would you treat a case of placenta prævia?
5. Give etiology, pathology, and treatment of puerperal eclampsia.
6. Give etiology, prophylaxis, and treatment of ophthalmia neonatorum.
7. Describe the care of a new-born babe.
8. Give treatment of post-partum hemorrhage.
9. Define involution and give causes for sub-involution.
10. Describe the menopause and give some conditions peculiar to that period.

GYNECOLOGY.

1. Describe the Sims' position.
2. What is meant by the term menstruation, and what are the two theories as to its relationship to ovulation?
3. Name the two general classes of amenorrhea, and give some of the causes under each class.
4. Give causes, symptoms, and treatment of metrorrhagia.
5. Give symptoms and treatment of vaginismus.
6. Name the most frequent of the uterine displacements. Give treatment of such displacement.
7. Give diagnostic points in small uterine fibroids.
8. What three lines of investigation must be considered in making diagnosis of uterine cancer.
9. Give causes, diagnosis, and treatment of cystitis.
10. Give symptoms and treatment of movable kidney.

SURGERY.

1. Give etiology, symptoms, and treatment of cholelithiasis.
2. Give etiology, diagnosis, symptoms, and treatment of abscess of liver.
3. Differential diagnosis of carcinoma from sarcoma of mammary gland.
4. Symptoms and treatment of laceration from the middle meningeal artery.
5. Give etiology and treatment of torticollis.
6. Give varieties of hip-joint dislocation.
7. Give classification and treatment of fistula-in-ano.
8. Give symptoms of floating kidney and describe *in toto* the radical operation.
9. What is known as fracture by "contre coup"?
10. Give symptoms and treatment of floating semilunar cartilage of the knee joint.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF FLORIDA.

Jacksonville, May 6 and 7, 1912.

ANATOMY.

1. The *fascia lata* is the deep fascia of the thigh, and invests the whole of the thigh.
2. The bones of the wrist are arranged in two rows: the upper row, from the radial to the ulnar side, consists of the scaphoid, semilunar, cuneiform, and pisiform; the lower row, from the radial to the ulnar side, consists of the trapezium, trapezoid, os magnum, and unciform.
3. There are no *bones of the larynx.*
4. *Portal circulation:* "The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary

tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins, which terminate on the posterior surface of the liver in the inferior vena cava."—(Bain's *Medical Practice.*)

5. CHAMBERS OF THE EYE: The *aqueous chamber* is a lymph space containing the aqueous humor and situated between the cornea in front and the lens, suspensory ligament, and ciliary body behind. The iris partially divides this chamber into an *anterior* and a *posterior* chamber, which are continuous through the pupil. The *anterior* chamber is bounded in front by the cornea and behind by the iris; the *posterior* chamber is a narrow chink between the iris, ciliary processes, and the lens.

6. *Organs in the peritoneal cavity:* Liver, stomach, spleen, part of duodenum, jejunum, ileum, transverse colon, sigmoid flexure, upper part of rectum, part of bladder, uterus, and ovaries.

7. *Articulation* is a joint, or connection between contiguous parts of the recent human skeleton.

Symphysis is a joint in which there is only very slight movement, and in which the contiguous bones are connected by a broad disc of fibrocartilage.

Synchondrosis is an immovable joint in which the contiguous bones are connected by hyaline cartilage.

8. *The ductless glands* are: Spleen, thyroid, parathyroids, thymus, suprarenals, carotid and coccygeal glands, and pituitary body. The *spleen* is situated in the back part of the left hypochondriac and epigastric regions. The *thyroid* is situated on the sides and in front of the upper part of the trachea, and extending upwards on each side of the larynx. The *parathyroids* are near (and behind) the thyroid. The *thymus* is (in early life) in the superior mediastinum and neck, reaching from the fourth costal cartilage to the lower border of the thyroid. The *suprarenals* are in the back part of the abdominal cavity, behind the peritoneum, one on the upper extremity of each kidney, and slightly also on the inner and anterior surfaces. The *carotid gland* is situated generally in the carotid bifurcation. The *coccygeal gland* lies near the tip of the coccyx, and in connection with the middle sacral artery. The *pituitary body* lies at the base of the brain, in the sella turcica of the sphenoid bone.

9. The *prostate gland* is a glandular structure surrounding the neck of the bladder and the first part of the penis. *Cowper's glands* are situated between the two layers of the deep perineal fascia, on either side of the membranous urethra. *Bartholin's glands* are small glands situated one on each side of the entrance to the vagina; it is analogous to Cowper's gland in the male. *Carunculæ myrtiformes* are the remains of the hymen after rupture of the latter structure.

10. *In a cross section of the body at the seventh cervical vertebra,* the following structures would be divided: Cricoid cartilage, lateral lobes of the thyroid body, trachea, esophagus, common carotid artery, internal jugular vein, pneumogastric nerve, sympathetic nerve, phrenic nerve, platysma myoides, longus colli, sternomastoid, vertebral vessels, trapezius, splenius, complexus, levator anguli scapulæ, scalenus anticus and medius, sternohyoid and sternothyroid.

At the sacro-coccygeal juncture: Rectum, small intestine, bladder.

PHYSIOLOGY.

1. *Metabolism* is the name given to the sum of the chemical changes which take place in the body and the tissues during life. Such changes as are constructive are called *anabolic;* such as are disruptive or destructive are called *catabolic.*

2. *Fats* are neutral bodies, consisting of triolein, tripalmitin, and tristearin. They all have glycerin for a base in combination with oleic, palmitic or stearic acid. They are derived from both animal and vegetable foods.

Fats are digested by the gastric juice dissolving the connective tissue and setting free the fat, which latter is emulsified in the small intestine by the steapsin of the pancreatic juice, and then enters the lacteals. It is also believed that fat is not absorbed as fat, but as glycerine and fatty acid or soap. From the lacteals it is conveyed to the thoracic duct, thence to the venous circulation. A little is also saponified and enters the portal vein.

3. *Normal fresh urine* consists of: Water, urea, uric acid, urates, hippuric acid, xanthin, hypoxanthin, creatin, creatinin, extractives; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen and carbon dioxide.

4. The *first sound* of the heart is heard best at the site of the apex beat; its cause is not settled, but the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves. (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The *second sound* is heard best at the junction of the third right costal cartilage with the sternum; it is caused by the vibration due to the closure of the semilunar valves.

5. By *normal blood pressure* is meant the pressure that the blood exerts (during health) against the wall of the vessel in which it is contained. It is ascertained by a manometer.

6. The normal temperature of the body is *maintained* by the thermotactic center in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. Heat is *gained* to the body by (1) the muscles, during contraction; (2) the secreting glands; (3) the brain, during mental activity; and (4) by the ingestion of food and hot liquids.

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretions (feces and urine).

7. The *functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the conversion of poisonous and harmful substances into inert material.

8. Proteins are nitrogenous organic substances, very complex, of unknown constitution, made up of carbon, hydrogen, oxygen, nitrogen, and generally sulphur; they may also contain iron, phosphorus, or some other element. They are acted upon by the pepsin of the gastric juice and the trypsin of the pancreatic juice.

9. *Respiration* is the process by which an interchange of gases takes place in the lungs; so that oxygen is introduced and carried to the tissues, and carbon dioxide is expelled.

The changes produced in the *air* by respiration are:

	INSPIRED AIR.	EXPIRED AIR.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide ..	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor.....	Variable.	Saturated.
Temperature	Variable.	That of the body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

"Respiration is carried on under ordinary circumstances by the diaphragm and external intercostals enlarging the chest and sucking air into the lungs, followed almost immediately by the recoil of the elastic lungs and ribs forcing out the air so inspired. But when there is a more than ordinary venous condition of blood in the system greater efforts must be made to supply the lungs with oxygen, and muscles not ordinarily employed in the effort must be brought into play. The arms and scapulæ are fixed by seizing hold of some object, and by bringing into action the trapezius, levator anguli scapulæ and rhomboidei, so as to make firm attachments for serratus magnus, pectorales, and latissimus in their efforts to raise the ribs. Labored expiration in like manner brings extra muscles into play. In labored respiration the nostrils are expanded by the dilatores naris during inspiration, and resume their original size during expiration. The glottis is widely open during inspiration, while it is narrowed during expiration. These movements of the glottis occur during ordinary breathing, but are exaggerated during difficult breathing."

"Breathing is a reflex act, capable of being modified by the will. The nerve-center is situated in the medulla, the *afferent* nerves are the vagi; the *efferent* nerves are the phrenics, intercostals, etc. Respiration continues in the absence of consciousness and after the removal of the brain about the medulla; but destruction of a certain small portion of the medulla below the vasomotor center causes the movements at once to cease. This spot is called *nœud vital.* The center is influenced by impulses from without or within—a dash of cold water in the face, a cold bath, an emotion, venous blood in the pulmonary vessels, all call it into action. The center is probably automatic as well as reflex, section of the vagi, thereby interrupting the channel by which the afferent impulses reach it from the lungs, while interfering with the respiratory act does not stop its action. Automatic impulses descend from the center along the efferent nerves. Probably the venous blood circulating through the center itself supplies the stimulus. (Ashby's *Physiology.*)

10. *Leucocytes* are the colorless blood corpuscles. They are *composed* of water and solids (proteids, leuconuclein, lecithin, histon, etc.). They differ much in appearance,

and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

CHEMISTRY.

1. The syllables *ous* and *ic* are used: (1) In naming acids, the one containing the more oxygen ending in *ic;* and the one containing less oxygen ending in *ous*. (2) In binary compounds *ous* denotes the compound containing relatively less of the more electronegative element than is found in the *ic* compound.

The syllables *ate* and *ite* denote salts; *ate* salts are derived from *ic* acids, and *ite* salts from *ous* acids.

2. $Na_2CO_3 + CaCl_2 = 2NaCl + CaCO_3$.

3. *Potassium* colors the Bunsen flame violet; *sodium* colors the Bunsen flame yellow; *copper* salts give a green color to the Bunsen flame (except the chloride, which gives a blue color).

4. *Treatment of carbolic acid poisoning:* Administer white of egg in water, or milk, or sodium sulphate in solution, or alcohol and water; follow by lavage.

5. *Symptoms of poisoning by belladonna:* "In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent; brilliant, with widely dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration."

Treatment: "Lavage of the stomach; morphine may be given cautiously during the period of violent excitement. Maintain respiration; strong coffee by the mouth or rectum is beneficial. Pilocarpine may be given, in not too large doses, to stimulate the secretion of saliva."—From Witthaus' *Essentials of Chemistry.*

6. *Symptoms of poisoning by cocaine:* Pain and fullness in the head, pulse at first quick but later feeble and slow; extremities cold. The symptoms are not constant.

Treatment consists in the administration of ammonia or coffee; morphine, strychnine, chloroform, and ether have all been suggested; artificial respiration may be necessary. The safest plan is to treat whatever symptoms are present.

7. In *chyluria,* the urine contains chyle, and is milky in appearance, or it may have a reddish tinge due to the admixture of a little blood. The milky appearance is due to an emulsion of fat. The condition is generally due to *filaria;* there is also a non-parasitic chyluria of unknown etiology and pathology.

"Under the microscope chylous urine shows no fat globules, or only a few, whereas urine containing milk is crowded with them. When chylous urine is shaken with ether the fat is extracted and the urine is left clear, or nearly so; when urine to which milk has been added is dealt with in the same way it is scarcely altered." (Mann's *Physiology and Pathology of the Urine.*)

8. *Reinsch's test for arsenic* is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

9. *Physical properties of phosphorus: Yellow* phosphorus is a yellowish translucent solid of the consistency of wax; below 32° F. it is brittle; at about 112° F. it fuses; at about 550° F. it boils; its vapor is colorless; exposed to air it gives off white fumes and produces ozone; it is luminous in the dark; it is insoluble in water, slightly soluble in alcohol, soluble in carbon disulphide and in the fixed and volatile oils. The *red* variety is not soluble in the solvents of the yellow variety, and is not luminous at ordinary temperature.

MATERIA MEDICA AND THERAPEUTICS.

1. *Chemicol incompatibility* may result in: (1) Production of a poison; (2) explosion; (3) double decomposition. In the following prescription double decomposition takes place, lead sulphate being precipitated, and zinc acetate remaining in solution:

℞. Plumbi acetatis ʒss
Zinci sulphatis gr. xv
Aquæ qs. ad ʒiv. Misce
Sig.: Use as an injection.

2. Cold reduces temperature by abstracting heat. It is best applied in the form of a bath, cold sponging, or ice-cap.

3.

CLASS.	EXAMPLE.	DOSE.
1. Emetic	Apomorphine hydrochloride	⅛ grain
2. Antispasmodic	Spiritus ætheris compositus	ʒj
3. Hypnotic	Choral hydrate	gr. xv
4. Expectorant	Syrup of squill	ʒss to ʒj

4. *Five antiseptics:* (1) Corrosive sublimate, 1:3,000 to 1:100; (2) carbolic acid, 1:40 to 1:20; (3) alcohol, 70 per cent., (4) lysol, 1 to 3 per cent.; (5) iodine, 1 per cent.

5. *Mineral tonics:* Iron, arsenic, mercury, calcium.

℞. Tincture ferri chloridi
Acidi phosphorici diluti *aa* ʒss
Syrupi simplicis q.s. ad ʒiij. Misce
Signa: One teaspoonful three times a day.

6. As a general rule, ether would be the anesthetic of choice. But chloroform may be used: (1) in hot climates; (2) when large numbers of persons have to be rapidly anesthetized; (3) in brain surgery; (4) in labor; (5) in patients who are known to take ether badly; and (6) in the conditions mentioned below, in which ether is contraindicated.

The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics: "Ether* should not be used by inhalation in bronchitis or acute nephritis because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

7. ERGOT. *Therapeutic indications:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headache, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

Contraindications: During the first stage of labor, and in anemia of the brain or spinal cord.

8. DIGITALIS. *Habitat:* Southern and central Europe. *Physiological effects:* It is a gastrointestinal irritant; it slows the rate of the heart, prolongs diastole, increases the force of the heart, contracts the blood-vessels, and causes a rise in blood pressure; it also acts as a diuretic.

9. IN MALARIA: (1) *Quinine* destroys the plasmodium malariæ. (2) *Worburg's tincture* acts by virtue of the quinine which it contains. (3) *Methylene blue* is believed by some to destroy the malarial parasite.

10. The *alkaline method in the treatment of rheumatism* consists in: The internal administration of sufficiently large doses of alkaline salts to render the urine quickly alkaline; in maintaining this alkaline reaction as long as

the rheumatic symptoms continue: and in gradually allowing a neutral or acid reaction to return by gradually diminishing the alkalies as the symptoms decline. It is claimed for this method that, as the alkalies begin to exhibit their action on the system, the whole aspect of the case becomes more favorable, the general distress being alleviated, the temperature falling, and the local symptoms relieved; that these favorable effects continue to become more and more marked, until the rheumatic condition has disappeared; that the average duration of the attack is greatly shortened; and that the proportion of visceral affections is much reduced. (From Quain's *Dictionary of Medicine.*)

OBSTETRICS.

1. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hicks' sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

2. *The fetal circulation:* "The arterial blood coming from the placenta to the fetus travels along the umbilical vein to the liver. After giving off several branches to the left lobe it divides into two streams, the larger joining the portal vein and thus entering the liver, the smaller passing directly into the inferior vena cava through the *ductus venosus.* In the inferior vena cava the blood carried by the hepatic veins and ductus venosus mixes with the blood which has circulated through the lower extremities. On entering the right auricle the blood of the inferior vena cava is directed by the Eustachian valve, through the foramen ovale into the left auricle, and from thence into the left ventricle. The left ventricle forces it into the aorta, and it is then distributed to the head and upper extremities, a small quantity only passing into the descending aorta. The blood which has circulated through the head and upper extremities returns to the heart along the superior vena cava, the blood then passing into the right ventricle and pulmonary artery. A small part of the blood in the pulmonary artery is conveyed to the lungs, but the major part passes through the ductus arteriosus into the aorta at the commencement of the descending portion. This blood is distributed to the lower extremities, a certain portion of it entering the hypogastric arteries and being conveyed to the placenta." (Ashby's *Physiology.*)

3. *Pelvimetry* means measuring the pelvis. For external pelvimetry some modification of Baudelocque's pelvimeter is generally used. In external pelvimetry four measurements are generally taken: (1) between the anterior superior spines of the ileum, normally about ten and a quarter inches; (2) between the external edges of the iliac crests, normally about eleven inches; (3) between the heads of the two great trochanters, normally about twelve and a quarter inches; and (4) between the spinous process of the last lumbar vertebra and the upper margin of the anterior surface of the symphysis pubis, normally about eight inches.

The diameters and measurements of the female pelvis are easily remembered from the following table:

	ANTERO-POSTERIOR.	OBLIQUE.	TRANSVERSE.
Brim	4 inches.	4½ inches.	5 inches.
Mid-plane	4½ inches.	4½ inches.	4½ inches.
Outlet	5 inches.	4½ inches.	4 inches.

4. *Treatment of placenta prævia:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of the cervix, version, and immediate extraction of the child.

5. PUERPERAL ECLAMPSIA is an acute morbid condition occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. *Etiology:* Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys. *Symptoms:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonos, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions. For *preventive treatment:* (1) The amount of nitrogeneous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. The *curative treatment includes:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

6. OPHTHALMIA NEONATORUM.—*Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

7. *Care of New-born Babe.*—"After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 or 2 drops of a 1% solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water. The vernix caseosa should be removed by means of some oily substance. The baby should be bathed in water at 100° F., carefully dried, and the cord dusted with some antiseptic powder. Sponging should be practised for 10 days, after which a full tub-bath at 98° F. should be given daily for 6 months. The temperature may then be reduced to 95° F., and at the end of a year to 90° F. The binder and clothing should be woolen. If the infant's extremities are blue or cold, external heat should be applied. The diapers should be made of flannel, and dusting-powders should be used to prevent chafing. An infant may be taken out-of-doors in summer when 1 week old, and in winter on pleasant days at 3 months of age. The new-born infant should sleep about 22 hours out of a possible 24, gradually diminishing this until at 2 years the child should sleep at least 12 hours of the day, and at 3 years not less than 11. The sleeping-room should be well ventilated.

In the care of premature or feeble infants there should be secured a temperature of 95° F., or slightly lower about the child, rigorous bathing should be avoided, and but little clothing applied. If the mother is unable properly to

nourish the child at the breast, artificial feeding must be commenced almost immediately."—(Gould and Pyle's *Pocket-Cyclopedia.*)

8. *Treatment of Postpartum Hemorrhage.*—Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

9. *Involution* is the process by which the uterus, after labor, returns as far as possible to its original size.

Causes for Subinvolution.—Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labor; misplacement of the uterus; retained clots or membranes; tumors of the uterus.

10. The *menopause* is the period when menstruation ceases. The symptoms of the menopause are referable to two stages; a stage of menstrual irregularity preceding the cessation of the menses, and a post-cessation stage of variable systemic disturbances. In normal or nearly normal cases the irregularities are not excessive; the systemic disturbances are slight. There is a period of unstable equilibrium. The woman may at times be unusually capricious and emotional; yet she passes through this physiological crisis with only a few minor disturbances. She may have the characteristic vasomotor flushes, perspiration, vertigo, somnolence, numbness, and faintness. The menstrual function ceases as it began, and other psychic disturbances are common in the abnormal cases, and may be exaggerated. The menstrual deviations vary in wide limits. The flow may gradually decrease and come at lengthening intervals until it altogether ceases; it may occur at short intervals or become continuous; it may become so excessive as almost to amount to dangerous hemorrhage; or life may be jeopardized by a slow, continuous drain. There is an increased tendency to malignant disease of the uterus and breasts during this period. The excessive fear of this may prey injuriously on the mind of the woman.—(From Dudley's *Gynecology.*)

GYNECOLOGY.

1. In *Sims' position*, the patient lies on her left side, with her head on a low pillow and turned on the left cheek. The hips should be at the left hand corner of the table. The knees are drawn up to the chest, the right one more so than the left. The left arm hangs down behind the body. The foot of the table should be a little higher than the head.

2. *Menstruation* is a periodic disturbance in the female, characterized by a bloody discharge from the uterine cavity; it occurs periodically during the time of the woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

3. Amenorrhea is the absence of menstruation. It is *physiological:* Before puberty, during pregnancy and early lactation, and after the menopause. Otherwise, it is *pathological,* and may be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold and various emotional causes. When due to anemia, chlorosis, etc., it is said to be *constitutional.* Amenorrhea is also called *primary* when the flow has never been established; *secondary,* when it is suppressed.

4. Metrorrhagia. *Causes.*—General diseases (such as scorbutus, hemophilia, acute fevers, nephritis, hepatic cirrhosis, heart disease); salpingitis, ovaritis, ovarian tumors, endometritis, endocervicitis, metritis; fibroids, sarcoma, carcinoma or polyps of uterus; prolapsed, retroflexed, or retroverted uterus; subinvolution. *Symptoms:* Hemorrhage from the uterus at other times than the menstrual period. *Treatment:* Ascertain and remove the cause if possible. Hot vaginal douches, ergot, astringents, and tampons have all been recommended. In case of malignant disease, hysterectomy may be necessary.

5. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, carunculæ myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

6. The most frequent of the uterine displacements are retroflexion and retroversion.

Retroflexion. *Treatment:* If there are no adhesions, the flexion should be corrected by digital manipulation and a pessary introduced; hysteropexy may be necessary.

Retroversion. *Treatment:* Remove the cause, if possible; replace the uterus and keep it in position by pessaries, tampons, and knee-chest position; pelvic massage and vaginal douches; proper hygiene, particular attention being paid to the bowels, clothing, and exercise. *Curative treatment:* The choice lies between ventral suspension of the uterus and shortening of the round ligaments.

7. *Diagnostic points in small uterine fibroids.*—Menorrhagia or metrorrhagia; often dilating the cervical canal and exploring the uterus is the only way of proving or disproving the existence of a fibroid. Pain, discomfort, leucorrhea, and lengthening of the cervical canal may also be present.

8. Hemorrhage, leucorrhea, and pain are nearly always present. Later on there may be an offensive odor.

9. Acute Cystitis.—(*a*) *Etiology:* Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold.

(*b*) *Symptoms:* Frequent urination, with tenesmus and a burning sensation in the urethra, later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

(*c*) *Treatment* includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

10. Movable kidneys. *Symptoms:* (1) Pain.—Uncomfortable sense of weight or movement in the loin. Dragging pain in the abdomen and back, worse during the menstrual periods. Occasional crisis of acute agony if the pedicle becomes twisted. (2) Gastrointestinal symptoms.—Dyspepsia and dilatation of the stomach possibly due to a kinking of the duodenum. Colic with constipation, or rarely diarrhea, from a dragging on the colon. Violent gastric crises of colic and vomiting from a dragging on a renal pedicle. Transient jaundice. (3) Urinary symptoms.—Slight albuminuria, pyuria, or hematuria from pyelitis or congestion. Polyuria, with ardent desire to micturate. Pain and scanty micturition, alternating with cessation of pain and polyuria, points to kinking of the ureter and hydronephrosis. Acute pain, passage of albumin, blood, and casts, point to torsion of the renal pedicle. (4) Nerve symptoms.—Hysteria, neurasthenia, melancholia, and hypochondriasis. Often worse during menstruation.

Treatment: (1) Palliative.—Indicated in: (1) Mild cases; (2) cases associated with hysteria or hypochondriasis; (3) general enteroptosis. Consists of: Rest, fattening diet. Belt with pad over kidney region; must be applied when the kidney is replaced.

(2) Radical.—(1) Nephropexy: When symptoms are severe and not relieved by rest and belts. When hydronephrosis is present. When renal crises occur. Result: 1-2 per cent. die; 90 per cent. are cured of the pain; 50 per cent. are cured of gastrointestinal symptoms. (2) Nephrectomy: Only when the kidney is disorganized by hydronephrosis or other disease. (From Grove's *Synopsis of Surgery.*)

SURGERY.

1. Cholelithiasis.—*Etiology:* Sedentary habits, catarrh of stomach and duodenum, microorganisms (*Bacillus coli communis*), obstructions to outflow of bile. *Symptoms:* "While the calculus remains free in the gallbladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochon-

driac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces."

Treatment "includes the relief of pain by morphine (gr. ¼) and atropine (gr. 1/125), hypodermically, inhalations of chloroform, hot applications, and blisters over the seat of pain, and, later, a saline purgative. During the interval the diet should be largely liquid, and drugs such as sodium phosphate, sweet oil, chloroform, piperazin, and mineral waters should be administered. Constipation should be avoided by giving fluid extract of cascara (5½) and glycerin (5½) every night. Lavage and rectal irrigation may be practised. If the attacks become more frequent and severe and medical treatment fails, surgical interference (cholecystotomy) is indicated." (Gould and Pyle's *Pocket Cyclopedia.*)

3. "From carcinomata, sarcomata are to be differentiated by the absence, as a rule, of lymphatic involvement, fixation of the skin and retromammary tissues, and retraction of the nipple. The nipple, though often displaced, is never retracted as it is in carcinoma." (Rodman's *Diseases of the Breast.*)

4. *Laceration of the Middle Meningeal Artery—Symptoms.*—"When not obscured by some other cerebral lesion, the typical symptoms are—(1) temporary concussion; (2) a lucid interval of a few minutes to a few hours; (3) gradually increasing drowsiness ending in coma. If the hemorrhage is rapid or there is cerebral laceration as well, there may be no interval of consciousness. In addition there may be, from pressure on the motor area, twitching of the corresponding parts followed by paralysis. The pupil on the injured side becomes first fixed and dilated, the other following. When the coma is well marked the pulse is slow and full, and the breathing is stertorous. When the brain is lacerated there are alternating tonic contraction and relaxation of the muscles supplied from the injured area.

"*Treatment* consists in trephining, removing the blood-clot, and stopping the bleeding. A flap is turned down, and a trephine hole made over a spot 1½ inches above and behind the external angular process exposes the anterior branch. After the blood-clot is removed the bleeding-point is searched for and tied; if it is not seen, more bone must be clipped away. If the bleeding comes from a canal in the bone, it may be stopped with gauze, sponge, or aseptic wax. If the brain then expands, the bone may be replaced and the wound stitched up without drainage; if not, the bone must not be replaced, and the wound should be drained for twenty-four hours. The posterior branch can be reached by a hole made just below the parietal eminence."—(*Aids to Surgery.*)

5. Torticollis.—*Etiology:* Cold, rheumatism, cerebral irritation, intrauterine lesion, paralysis, hysteria. *Treatment:* Remove the cause, treat any neurosis, give antispasmodics; stretch or sever the spinal accessory nerve or posterior cervical nerves; massage, tenotomy of sternomastoid.

6. *Varieties of hip joint dislocation.*—(1) Backward on to the dorsum ilii; (2) on to the sciatic notch; (3) on to the obturator foramen; (4) on to the pubis.

7. Fistula in Ano.—*Classification:* There are four varieties: (1) The *complete*, which opens into the rectum internally and on the perineum externally; (2) the *external incomplete*, or *blind external*, which opens on the perineum but not into the rectum; (3) the *internal incomplete* or *blind internal*, which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

Treatment: This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days, and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze." (Stewart's *Surgery.*)

8. See above Gynecology, Question 10.

9. *Fracture by contre-coup* is a fracture of the skull on the opposite side of the head to that which receives the blow.

10. Floating Semilunar Cartilage of the Knee Joint.—*Symptoms:* "Violent pain in the knee joint, chiefly on the inner side over the lateral ligament. The knee is locked in a semi-flexed position. Synovial effusion with its usual signs appears within a few hours. Later, and in the absence of proper treatment, recurrent attacks of synovitis often occur in any action of flexion and rotation of the knee. Tenderness is most marked on pressure over the tibial attachment of the internal lateral ligament. Very rarely a lump or gap can be felt in the position of the cartilage."

Treatment: "Reduction by flexion and extension of the joint. Immobilization on a back-splint for six weeks, followed by firm bandaging for three months. This treatment should be adopted in all recent cases occurring for the first time. Operation (for all recurrent cases): If thorough immobilization has been neglected at first, it is useless later. Incision in a transverse direction over the edge of the affected cartilage. Open the joint. Remove completely all injured or displaced parts of the cartilage. Cut any tags of hypertrophied synovial membrane. Close without drainage. Retentive apparatus (when operation is refused or undesirable in chronic cases): The mechanism embraces the joint and while allowing flexion does not permit of any rotation." (Grove's *Synopsis of Surgery.*)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Harelip and Cleft Palate. By James Berry, B.S., F.R.C.S., and T. Percy Legg, M.S., F.R.C.S. 324 pages, with 242 figures; cloth; price $4.00. P. Blakiston's Son & Co., Publishers, Philadelphia.

Text Book of Microscopic Anatomy. By Albert Edward Schafer, LL.D., Sc.D., M.D., F.R.S. 739 pages; illustrated; cloth, with 1,001 engravings and 21 colored plates; price $7.50 net. Longmans, Green & Company, Publishers, New York.

Common Disorders and Diseases of Childhood. Second Edition. By George Frederic Still, M.A., M.D., F.R.C.P. 813 pages; illustrated; cloth; price $5.50. The Oxford University Press, Publishers, New York.

Studies of the Department of Pathology of the College of Physicians and Surgeons Columbia University, New York. Vol. XII. For the Collegiate Years 1909-1911. 209 pages; illustrated; paper.

Baby's Teeth to the Twelfth Year. By Albert Westlake, DD.S. 35 pages; cloth; Mitchell Kennerley, Publisher, New York and London.

Psychotherapy. By James J. Walsh, M.D., Ph.D. 806 pages; cloth. D. Appleton & Company, Publishers, New York.

Outlines of General and Surgical Nursing. By Winifred Frederick Lindsay. 114 pages; cloth. The College Press, Publishers, Loma Linda, Cal.

Traite International de Psychologie Pathologique. By Dr. A. Marie. 1038 pages; illustrated; paper; price 25 francs. Librairie Felix Alcan, Publishers, Paris.

The Healthy Baby. By Roger H. Dennett. 228 pages; cloth; price $1.00 net. The MacMillan Company, Publishers.

Aids to Histology. By Alexander Goodall, M.D., F.R.C.P. 133 pages; illustrated; cloth; price $1.00 net. William Wood & Company, Publishers, New York.

Aids to Ophthalmology. By N. Bishop Harman, M.A., M.B., F.R.C.S. Fifth Edition. 216 pages, with 100 illustrations; cloth; price $1.00 net. William Wood & Company, Publishers, New York.

Gynecological Nursing. By Arthur E. Giles, M.D., B.Sc., F.R.C.S., M.R.C.P. 187 pages, with 41 illustrations; cloth; price $1.50 net. William Wood & Company, Publishers, New York.

Medicolegal Notes.

Testifying as to Effect of Condition.—On the cross-examination of a medical expert witness it is permissible for the purpose of testing his skill and accuracy to ask the witness pertinent hypothetical questions, based on facts having no foundation in the evidence. A plaintiff in a street railway accident had testified that she had sustained certain nervous disorders. A physician who treated her was introduced as a witness by her, and on direct examination testified both to facts relating to her injuries within his knowledge and to matters of expert opinion. On cross-examination he was asked such questions as, assuming that the plaintiff had had fainting spells prior to the accident, and that she had had an attack, or had been suffering for some time before the accident from gallstones and that her complexion was very yellow, if he could tell as a physician whether or not that condition might in any way affect her nervous system. It was held that such cross-examination was admissible.—Conway v. Metropolitan Street Ry. Co., (Mo.) 142 S. W., 1101.

Physician Claiming Privilege Not to Answer.—In an action for a negligent death, a physician testifying for the defendant was asked to state what he had treated the decedent for some five or six years before the accident. He refused to answer, claiming that it would be improper to disclose information acquired by him in his professional capacity. The trial court declined to compel the witness to answer unless there was an express waiver by the plaintiff. No express waiver was made and the question remained unanswered. The New York Appellate Division held that while it was true that the privilege claimed by the physician did not belong to him, but to the patient, who could have waived it, and though technically the physician was claiming a right which he did not possess, yet the refusal of the court to compel him to answer was not reversible error where it did not appear that the evidence sought was material to the question to be determined.—Trieber v. N. Y. & Q. C. Ry. Co., 134 N. Y. Supp., 267.

Privileged Communications—Termination of Relation of Physician and Patient.—The physician who attended the plaintiff suing for injuries received in an accident was, while upon the witness stand, questioned by the defendant as to statements which he had heard the plaintiff make a short time before the trial in regard to his injuries. This was objected to as calling for a privileged communication, and the objection was sustained by the trial court. This ruling was complained of on appeal, for the reason that the relation of physician and patient had terminated a long time before the statements of plaintiff which it was sought to prove, and that, therefore, the question was not privileged. It appeared that two other physicians employed by the defendant were examining the plaintiff, and the plaintiff's former physician was called in by these others. The plaintiff still regarded him as his physician, and objected to his assisting the physicians employed by the defendant in obtaining evidence. The other two physicians testified to what took place upon their examination. It was held that it was not an abuse of discretion to exclude the evidence as privileged, the plaintiff's statements to his former physician being apparently still regarded by him as confidential. —Neice v. Farmers' Co.-op. Creamery Co., Nebraska Supreme Court, 133 N. W. 878.

Burden of Proof of Insanity.—A contestant of a will on the ground of mental incapacity has the burden of overcoming the presumption that everyone is sane. If he shows that the subject of the injury was habitually insane before the paper was attempted to be executed, the burden, it is said, then shifts to the proponent to show that the will was made during a lucid interval. But if habitual fixed insanity prior to the act in question is not shown by the contestant the burden does not pass to the proponent.—Johnston v. Johnston, Alabama Supreme Court, 57 So. 450.

City Hospital Charitable Institution Though Charging Fees.—A petition in a suit against a city alleged that the plaintiff was injured in consequence of being struck by an ambulance which was negligently driven against him while he was in the exercise of due care. It appeared from the remainder of the petition that the ambulance belonged to and was being operated for a public hospital of the city which was under its control through its board of officers. It was also averred that in the maintenance of the hospital the city "charged fees for patients entering therein." It was held that the petition was demurrable, the last averment not being tantamount to an allegation that the city maintained and operated the hospital for pecuniary gain and private profit.—Watson v. City of Atlanta, Georgia Supreme Court, 71 S. E. 684.

Medical Items.

Treatment and Prophylaxis of Scarlatina.—Rouéche states that there is no specific treatment for scarlatina at the present day. Serum treatment for curative or prophylactic purposes has as yet been unsatisfactory. It is necessary to use all hygienic measures to insure the resisting powers of the patient and to apply symptomatic treatment as heeded. The feeding should be a modified milk diet, absolute as long as the fever lasts, and then replaced by soft foods not containing proteids. The use of a salt-free diet, deprived of salt, consisting of potatoes, sugar, butter, and meat without salt, causes lessening of weight, with diuresis and regular elimination of chlorides and urea. If salt is allowed the loss of weight occurs later in the disease. With milk alone the loss of weight is less, and the elimination more regular. As to the treatment of symptoms, too much throat and nose treatment has often been given; this should be confined to mild antiseptic washes gently applied. No antithermic remedies should be used. The best prophylactic measure is absolute isolation in a separate box, if the case is in a hospital, it being found that in general contagious wards diseases are spread to uninfected cases. Everything used by the patient should be disinfected before it leaves the room, and less stress should be laid on the disinfection of the room itself. The length of the isolation should vary with each case. There are cases in which the disease is not contagious after a few weeks, and others in which the contagion remains in the throat and ears for more than forty days. There are carriers of germs who should be pursued and isolated to prevent the spread of the disease.—*Journal de Médecine de Paris.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 5, 1912:

Places	Date	Cases	Deaths
CHOLERA			
China: Amoy	June 1	..	..
Swatow	June 1	.	..
Sporadic cases, occurring in the port.

THE EXTERNAL USE OF WATER FOR ENHANCING RESISTANCE IN TUBERCULOSIS.*

By SIMON BARUCH, M.D.,

NEW YORK.

PROFESSOR OF HYDROTHERAPY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

THE renaissance of tuberculosis management was initiated by Brehmer of Goerbersdorf, who, in the face of criticism, ridicule, and obloquy persisted in the claim that tuberculosis is curable by the physiological agencies—air, water, exercise, rest, and diet. These remedial agents are fully treated in every American work, and they have been the frequent theme of discussion in this society—*with the exception of water.* It is the purpose of this paper to rescue water from unmerited neglect and to show that the latter originates in unfamiliarity with the principles and practice of hydrotherapy. In 1892 I presented to the New York State Medical Society an address on "The Successful Management of Chronic Diseases," in which the value of the methodical application of remedies, and especially of water, was distinctly brought out. *Pulmonary tuberculosis* was selected as a striking illustration of my theme. The marvelous results from the methodical graduated, application of cold (below skin temperature) water in phthisis pulmonalis was demonstrated by clinical histories from the records of the Montefiore Home for Incurables (now called Home for Chronic Invalids and Hospital for Consumptives). I indulged in no generalizations but sustained every statement by bedside facts, citing cases in all stages of the disease in which the improvement in nutrition and gain in weight and general vigor was phenomenal, resulting in return to their vocation in some instances and even in remaining capable of work for several years.

These patients were under constant observation of some of the staff of eighteen physicians, their sputum was examined by Dr. Hodenpyl, pathologist to several hospitals; there was no possibility of error. In none of them, and I want particularly to emphasize this fact, did the open-air treatment, the most potent of all antituberculosis remedies, play a rôle. For despite the fact that in the planning of the building I had insisted upon a costly and perfectly equipped Liegehalle, heated in winter and opening to the South, it proved impossible to induce these desperate people to submit to discipline by reason of the mistaken kindliness of the directors, whose chief aim was claimed to be to soothe their dying days. Nor did I interfere with the medication even when it did not meet my approval. In view of these facts, it may be claimed that *the favorable results were chiefly due to the methodical application of water* and the good food for which they would have had no appetite without the tonic action of the latter. Moreover, they had, previous to admission, been treated secundem artem in our best hospitals and by competent private physicians and consultants, with the sole exception of water, which at that time was not systematically used by anyone in this country.

Seven years later our worthy colleague, Dr. Adolphus Knopf, published his excellent work on tuberculosis, in which he described several procedures and emphasized their importance. Since that time I have come across only three books on tuberculosis by American authors which make mention of the subject. One displays contempt and absolute ignorance of the uses of water despite the fact that its 300 pages are an otherwise good work. This author writes: "Well selected tonic medicine is worth incomparably more than baths. Unfortunately, most experimentations with baths have been done by specialists in hydrotherapy, a circumstance not conducive to unbiased reports." The absurdity of this comment would reveal itself to the author even if he would replace the word baths by tuberculin and hydrotherapy by tuberculosis. Compare this tirade of a man ignorant of hydrotherapy to the encomiums of a great teacher like Von Ziemmssen, of Brehmer, Dettweiler, Cornet, and others who gratefully commend these "specialists" and you will not regard my comment unwarranted.

A second more pretentious and in other respects able work does not mention hydrotherapy except to state that "dietetic and hydropathic means often suffice to cause disappearance of night sweats." This author's dread of water is amusing; he never advises it without adding vinegar, alcohol, chloral, or brandy, a practice which Von Ziemmssen very properly condemned long ago.

Another textbook on tuberculosis, consisting of contributions by American authors, dismisses water with a few vague lines on cold baths "for hardening and mustard foot baths and sponging for temperature reduction." None of these latest American works mention the principal action of water—improvement of nutrition and stamina. Contrast Knopf or Cornet or any complete work, or the views of Brehmer, the father of phthisiotherapy, with these authors and you will fall into sad reflections on the lack of knowledge of American tuberculosis authorities on the subject of hydrotherapy. The latter is also illustrated by the following incident—I cite it to sustain my contention. During a recent visit to a magnificent hospital for tuberculosis now in course of construction, I found that each floor of the six pavilions was supplied with a

*Read before the National Association for the Study and Treatment of Tuberculosis, at Washington, D. C., June, 1912.

complete douche room which, among other features proving ignorance of technique, was arranged so badly that the doucheur would receive water rebounding from the patient. There were twenty-four douche rooms for 600 patients! Expressing surprise at this lavish expenditure, the architect explained that he had been informed that a hydrotherapeutic plant was essential in every up-to-date tuberculosis hospital, and since he aimed to excel all other institutions, he placed a douche room in every ward so that the most helpless patients would not be deprived of the beneficent water treatment. He certainly is building an institution which is complete and praiseworthy in every other respect except in cost. My comment that one douche room would probably suffice for the entire institution, since it is intended for advanced cases, and would therefore present but a small percentage of ambulant cases fit for the douche, was met with the statement that none of the tuberculosis experts who had examined the plans and had inspected the hospital since the douche rooms were actually laid out had criticised the latter, though they had not spared him in other respects. Nor was he entirely satisfied until I had shown him the Riverside House Hydriatric Department, in which 100 to 150 treatments are sometimes given in ten hours in one douche room and the Vanderbilt Clinic Hydrotherapeutic Department, in which twenty-five patients are often disposed of in two hours. About $120,000 was the cost of this unnecessary douche room arrangement besides the valuable space wasted. This expenditure applied to incipient cases would restore many to health and earning capacity.*

Another mistake which will do much damage if this warning be not heeded and which I pointed out in vain to the architect was the instalment of an electric light cabinet in each douche room. This apparatus is useful chiefly for rapid production of diaphoresis and its suggestive effect. The former is exhausting and therefore injurious and the latter is unnecessary in the advanced stages of tuberculosis. It is hoped that the physicians who will take charge of this great hospital may study hydrotherapy in some good textbook before they venture to utilize the still abundant facilities for hydrotherapy.

Now for the other side of the picture. I was delighted to note that this society has not been altogether oblivious to the upbuilding action of water. True, this agent is rarely referred to in the transactions, but whenever Knopf, Pottenger, Meyer, and Barlow have spoken they have displayed a correct idea of its aims. At every meeting climate, exercise, diet, rest, tuberculin have been fully discussed. At only three meetings do I find water mentioned and then in the most casual manner.

I plead to-day for the restoration of this potent agent for enhancing resistance to the legitimate position assigned to it by Knopf, who wrote "hydrotherapy comes next to aerotherapy."

*The fallacious idea that a hydrotherapeutic plant is essential to an up-to-date hospital often comes under my notice, since I am frequently consulted on this subject. Only a few months ago the plan of an extensive Hydrotherapeutic Department for a hospital of 500 patients was submitted to me for revision and suggestions. I advised against it because there was no large outdoor department. In another costly hospital my advice to the same effect was disregarded; the apparatus has never been used.

†This paper was allowed twenty minutes, while most of the afternoon was devoted to three papers on tuberculin, the value of which was shown by excellent observers as dubious.

For forty years water below the skin temperature has been constantly a part of my therapeutics of pulmonary tuberculosis. Prior to 1880 a residence in Camden, S. C., brought a number of these cases under my observation; its proximity and climatic similarity to Aiken made this town quite a resort for consumptives. Not, however, until I became chief of the medical staff of the Montefiore Home for Incurables did an opportunity present itself to utilize water on an extensive scale and with intelligent cooperation. In 1886 a small appropriation was ironically granted me by the directors, who regarded the restoration of any of these incurables as chimerical. The astounding results obtained in phthisis and other intractable diseases brought a larger appropriation and contributed no little to the change of title from "Home for Incurables" to the present title. The records of this institution tell their own story. Some of them were published four years before I visited Goerbersdorf and Falkenstein. My faith in water for enhancing resistance was nurtured by Von Ziemmssen's classical lectures on Phthisis Pulmonalis. In the tenth lecture he said: "I cannot close this chapter on prophylaxis without mentioning hydrotherapy, which here as well as in developed tuberculosis plays an extravagantly important rôle. I recommend for your special study Winternitz's excellent monograph on this subject. My observations are in entire accord with those of Winternitz."

"Water is the most simple strengthening and hardening remedy; it may be used everywhere and by everyone. Even the most simple lukewarm rubbing down of the entire body on leaving bed (reduced as he describes later) exercises the nerves and muscular system and conduces to prompt reaction, refreshing and stimulating the nervous system and reflexly the respiration, circulation, and digestion. It may be used in the poorest families. There is no advantage in brandy and salt rubs. The shock-like action is demanded. The great advantage of cold rubbing is that it may be applied at home by even an inexperienced person and its good effect may be obtained for months and years by daily practice, especially among the less well-to-do, all of which give it extraordinary value."

The present generation of physicians cannot realize the high standing of Von Ziemmssen as a clinical teacher and observer; to my youthful mind his dictum was gospel, and I have had no cause to regret this faith. When I visited Brehmer's, Roempler's, and Dettweiler's Sanatoria in 1896, it appeared to me that the douche was given at too low a temperature (it was 47° F. at Falkenstein) and too strong from a large shower. I was informed in reply to this comment that only patients already improving were judiciously subjected to this douche, and that the reaction was cautiously guarded. In the Montefiore Home, on the contrary, which at that time received no incipient cases, almost all patients received mild neurovascular training; *i.e.* the graduated application of cold water. Thus was happily demonstrated the superiority of the mild procedures over the heroic douche method.

I have coined the term "Neurovascular Training" in order to emphasize the fact that there are few, if any, cases that may not be profitably subjected to a graduated, daily increase of cold water, reducing the temperature, and increasing the duration slowly and, in institutions, adding the pressure from the douche. By this method the capacity of the nerves and vessels of the skin and its muscular structures

which control the capillaries may be trained to respond with increased vigor just as the muscles of the arm may by slow and graduated accretion of weight be trained to lift heavier weights.

The following syllabus prepared for the students of my department, briefly describes Neurovascular Training:

VANDERBILT CLINIC.
DEPARTMENT OF HYDROTHERAPY.
TONIC HYDROTHERAPY.

Graduated Neurovascular Training. Cardinal rule.—All water applications below 90° F. must be made with friction.

First Stage—Ablution.—Avoid extremities below knee and elbow. (*a*) Begin with 90° with saturated linen cloth or gloved hand. (*b*) Pass rapidly over successive parts. (*c*) Dry thoroughly. (*d*) Dress and exercise in open air in ambulant cases. (*e*) Reduce temperature of water daily two or more degrees, until 60° is reached.

Second Stage—Affusion.—(*a*) Patient stands in water at 105°. (*b*) From a bucket of water at 85°, water is dipped and thrown over back, each shoulder and chest. (*c*) Dry, dress and exercise in open air. (*d*) Reduce water temperature daily 5° or more to 60° F. (*e*) If reaction is good, proceed to third stage.

Third Stage—Cold Rub.—(*a*) Patient stands in water at 105° F. (*b*) A linen sheet is wrung out with water at 80°, decreased daily. (*c*) Damp sheet is wrapped over body snugly. (*d*) Patient is actively rubbed over sheet until sheet is warm. (*e*) Dry, dress and exercise in open air. (*f*) Reduce temperature of water 5° to 10° daily to 50° if reaction is good. Then proceed to drip sheet.

Drip Sheet.—(*a*) Patient stands in water at 105° F. (*b*) Upper edge (12 inches) of linen sheet is gathered into folds. (*c*) Sheet is dipped in water at 80°. (*d*) The dripping sheet is held by attendant while patient wraps himself into it by turning the body. (*e*) Friction and slapping with flat hands for two minutes. (*f*) Pour water at 70 degrees over shoulders. Rub and slap again until sheet feels warm. (*g*) Repeat this over successive parts of body, rapidly. (*h*) Sheet removed. Patient dries, dresses, and exercises. (*i*) Reduce water temperature daily until 50° is reached.

In small sanatoria and in private practice the douche may be replaced by the drip sheet.

I heard a teacher of hydrotherapy in Vienna say "the douche must always be given strong and cold." The application of the douche in this indefinite manner has done much harm. Especially in tuberculosis is it fraught with mischief and this *has done much to discourage its popularization.* In careful, skilled hands this idea would exclude many feeble patients, while in careless hands life and health would be endangered. Brehmer dwelt on this danger, insisting that the douche be always administered by a physician. I apprehend that despite his praise of this procedure his just caution has deterred many from its use in appropriate cases. With the apparatus I have devised for institutions, the duration, pressure, and temperature may be so accurately applied that the patient may be gradually trained to accept it without harm. This is proved by some of the Montefiore Home patients who were so well trained by the graduated hydrotherapy preceding the douche that they refused a five-minute rain douche of higher temperature than 65° F., a procedure from which most of us would shrink. That this douche table is absolutely "foolproof" is evident from a record of over 50,000 treatments in three institutions during the past twenty years. For tuberculosis cases in institutions I have devised a more simple and less expensive wall apparatus.

The difference between the slow and cautious neurovascular training and the heroic douche treatment is illustrated by two sanatoria that are under equally skilled direction. In the Budapest St. Elizabeth's Hospital Dr. Kuthy uses the former; he reports one thousand cases in the first stage treated with tuberculin and the most approved dietetic and hygienic régime, of which 53.9 per cent. were discharged as clinically cured, while at the Belzig Sanatorium only 39 per cent. recovered. The only difference in the management of patients in these institutions was that Kuthy used a graduated hydrotherapy adapted to each patient's condition from the beginning, while at Belzig the douche is the principal procedure. Kuthy does not regard any case as cured until two years have elapsed without manifestations. These data are cited to show that individualization is important and that although both physicians individualize carefully one loses the best action of water because he awaits, as did Dettweiler, the patient's tolerance of douches.

Unfortunately for its universal adoption, water is used irrationally on merely empirical grounds. A rational basis underlies its action. What is the rationale of water in tuberculosis? Taking pulmonary tuberculosis as an example, the indications are to improve nutrition and hematosis, to elevate the patient's stamina in order to enhance resistance. During the last quarter of a century I have not prescribed medicinal tonics for any patient because systematic neurovascular training which may be administered in any household, has been effective in the improvement of appetite, increase of blood cells, and muscular and circulatory capacity, as evidenced often in gain of weight and general vigor. This statement is based on hundreds of blood-counts and weight records. The rationale is so simple that I would fain omit it here, were it not invariably disregarded in the text books which detail the action of medicinal agents at length. The so-called shock from cold water is dreaded without reason; it is not, like surgical shock, "a depression of the vital powers," but rather a surprise to the cutaneous nerve terminals, furnishing thermic and mechanical excitation which, as we learned in our student days, is conveyed to the central nervous system and thence reflected upon all the structures in connection with the latter. Pardon my using a trite but emphatic illustration—the gasp of a stillborn infant on receiving a dash of cold water. In fact the management of this type of "asthenia" offers an epitome, as it were, of hydrotherapy. Do we not increase the dose of temperature stimulus by dipping the entire body in cold water, when the smaller dose—sprinkling—fails to arouse the waning vitality, and do we not again increase the so-called shock by contrast of the alternating action of hot and cold water dipping, when needed to resuscitate the patient? Alcoholic or medicinal stimulants are not thought of in this sudden demand upon our therapeutic resources. Why has custom established cold water as the only stimulant in this most pathetic of all asthenias? Because the empirical good results are based upon rational physiological principles and no other stimulant is capable of accomplishing such marvels of restoration. You may apply the principle here involved—*temperature excitation judiciously adapted*

to the patient's reactive capacity—to every other form of asthenia. In tuberculosis, for instance, you may obtain precisely the same effects for the same reason. This is true science, more than can be said of some of our "best remedies." Individualization is imperative; its neglect brings disappointment and failure, often resulting in abandonment of an agent that has possibilities unthought of. That the dash and the dip would be futile in typhoid asthenia and that the cold bath would be fatal to the infant "goes without saying." I have formulated a hydrotherapeutic law—the effect of a hydrotherapeutic procedure is governed by the difference between skin and water temperature. This is modified by psychic and physical conditions which are easily learned by a little observation and practice. To avoid faulty hydrotherapy and make it more universal, I have devised neurovascular training which furnishes a daily test of reactive capacity and by which all harm may be obviated in the most depreciated case. The effect of neurovascular training upon the circulation is marked by reason of the vasomotor stimulation which primarily affects the smaller vessels. In addition there is an action upon the "skin heart" which has not been sufficiently appreciated. I hold that since the capillaries have no muscular nor elastic coat, their narrowing under cold water is due to the cutaneous muscular fibers which are contracted by the cold. These compress the capillary network with which they are interwoven and thus aid the vasomotor action by increasing the resistance at the periphery. The result is an immediate response of the heart with increased ventricular contraction and all the potent influences, flowing free from an enhanced cardiac tone, removal of stases, exudates, and enhanced nutrition and elimination. Moreover, the well-known favorable action of cold procedures in other infectious diseases evoked by their effect on the peripheral circulation may be expected in tuberculosis also. This is the clinical fact observed in febrile cases especially.

Before Plunge, 50 Contractions. Raised 5.139 kgm.

Fig. 1—Normal fatigue curve right hand.

After Plunge 50° F. 74 Contractions. Raised 9.126 kgm.

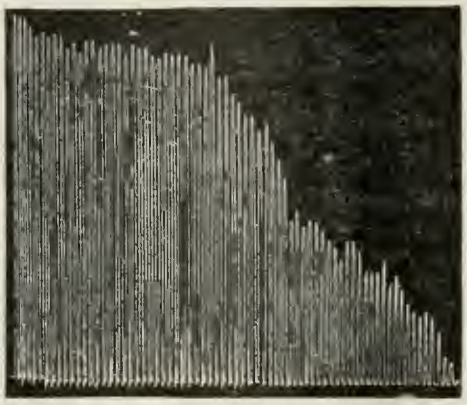

Fig. 2.—Fatigue curve, right hand, after bath, 50° for 15 seconds.

Ergograph Tracings. (Maggiora.)

There is one action of water procedures which has not received sufficient attention, viz., the remarkable influence of cold and warm water upon the muscular system. Vinaj and Maggiora of Turin have given us some valuable laboratory data on the enhancement of muscular vigor by cold water and its diminution under warm water if given without the mechanical stimulus of atmospheric pressure. By repeated experiments with the ergograph of Mosso, to whom they submitted their results, they ascertained the fatigue curve (line) before and after water procedures of various kinds. The middle finger of the right hand, for instance, was made to contract with the greatest exertion, lifting a weight of one kilogram until fatigued; the point of exhaustion was reached after fifty contractions, two seconds apart. (Fig. 1.) This was calculated to correspond to a total of 5.139 kgm. work, while after a plunge bath of 15 seconds at a temperature of 50° F, the same finger was capable of completing 74 contractions before fatigue ensued, corresponding to 9.126 kgm. work.* (Fig. 2.)

Fig. 4.—*a*, Normal fatigue curve; *b*, After labor; *c*, After wet sheet.

a b

Fig. 3.—*a*, Before rest, or before wet sheet: *b*, After rest, or after cold wet sheet.

In an interesting article on the rationale of rest published in the May number of the *Outdoor Life* by Professor Lee of Columbia University, the effect of rest is shown in a diagram which I reproduce (Fig. 3) in order to show that a similar effect is produced by cold water procedures. In Figure 4a and b the fatigue lines are shown after muscular action; Figure 4c shows how the lost muscular vigor was restored by the cold wet sheet.

Professor Lee writes "There is no known antidote for fatigue (with its detrimental products) unless it be rest." Figure 4 demonstrates that there *is* another antidote and a much more powerful one, namely cold water administered with friction. The chief physiological action of cold water procedures is first the beneficent effect of exercise upon the unfatigued muscle and second the good effect of rest upon the fatigued muscle. We therefore obtain from judicious graduated cold procedures an improvement in the circulation of the blood and lymph, enhancing cardiac activity and

*From "Principles and Practice of Hydrotherapy," Wm. Wood & Co., New York.

driving the venous and arterial blood and the lymph through unwonted channels, washing out fatigue products and other elements of defective tissue change. The advantage of muscular enhancement by water over that produced by active muscular exercise in tuberculosis is enormous, because there arises no active disturbance of the respiratory process which would menace the consumptive. Too often also absolute cessation of exercise is demanded by reason of rise of temperature leading to loss of valuable tone, when cold water proves a precious substitute.

My limits do not permit me to enlarge upon the rationale of the action of judicious and graded hydriatric procedures; these are fully detailed in Chapter V of my book on "Principles and Practice of Hydrotherapy," Third Edition, Wm. Wood & Co.

When all its briefly enumerated effects are considered, it may be claimed without fear of contradiction that hydrotherapy would occupy a high plane in the management of tuberculosis if it were applied rationally as is here outlined. Owing to the lack of training, faulty methods prevail in otherwise excellent institutions in which *the good results now obtained would be vastly multiplied by improved methods.* For instance, in one large institution the patients are permitted to take their showers as suits them, while in another the patient stands on a glazed brick floor with the cold water flowing upon his feet; the latter should always be protected by a slat floor because their chilling interferes with general reaction. Moreover the shower is not so stimulating as the fan douche which strikes every part treated with friction and may be confined to definite portions of the body, as demanded by reactive capacity.

The wonderful results of graduated exercise claimed by Marcus Patterson of the Brompton Hospital for Consumptives are the result of judicious gradation. He applies exercise as I have applied water, beginning with mild forms and slowly, carefully rising to more active methods. This is the secret of success and it is simple enough to enlist imitation.

Another precious advantage of systematic water treatment of tuberculosis lies in the fact that when the patient returns (cured or arrested) to his unfavorable environment, the daily neurovascular training has become an imperative need for him. Dr. Rosenberg of Bedford Hills informs me that he often meets discharged patients who express their craving for the shower bath which they satisfy in the public baths where showers are the rule. They are not always able to sleep with open windows because other inmates of the room object to cold air, but they can readily obtain the cold shower and protect themselves against relapses by enhancing resistance capacity in another way.

In conclusion I would say that these comments are the result of my disappointment in finding hydrotherapy discussed so little in American books upon and societies connected with tuberculosis. If colleagues are using it they have failed to realize its importance and have not published their results. I hope that to-day's discussion may be confined to actual clinical or laboratory investigations, as I have endeavored to present.

I have been more frank than is my wont, because of the pressing demands of suffering humanity, and having passed the biblical span of life another opportunity may not be granted me. This is my warrant for urging upon every tuberculosis specialist to investigate the rationale and therapeutic action of water and to try in every case the method of neurovascular training which may be practised in the most humble household upon the most depreciated subjects without harm in this as in other depreciated conditions.

I am ready to demonstrate all I claim to any one interested in the subject, in the institutions and clinic with which I am connected.

TREATMENT OF HABITS.*

By CHARLES E. ATWOOD, B.S., M.D.,

NEW YORK.

NEUROLOGIST, HOSPITAL AND SCHOOLS FOR CHILDREN, RANDALL'S ISLAND; ASSISTANT IN NEUROLOGY AND PSYCHIATRY, VANDERBILT CLINIC.

This subject having been selected for me by the Committee of the Orthodontia Association, will have to be discussed by me largely in its generic sense and from a biological standpoint. In this way perhaps some suggestions may be brought to light which can be adapted to practical ends in dealing with the pernicious habits which interfere with the important work of your specialty.

According to the Mendelian law, very simply stated, one-fourth of the offspring of a given union will be like one parent, one-fourth like the other, and one-half will be of a mixed type, partaking of characteristics of both parents and capable of further transmitting these characteristics in turn to their children. Investigations into the heredity of insanity, feeble-mindedness, epilepsy, and the neuropathic constitution, have already been made; and in the study of generations of many families in reference to the probability of inheritance of neuropathic conditions, the actual findings have corresponded with astonishing closeness to the theoretical expectation expressed in the Mendelian theory. It would take too much time and space, however, to discuss the matter at length. According to the same law, variations acquired during the life of an individual are not transmitted to his descendants. It is nevertheless true that descendants are not exactly like ancestors and not exactly like each other. On the theory of evolution we may attribute this variation to natural selection; while heredity helps to perpetuate what natural selection has caused to survive. Environment is a factor in producing inharmonious variations from the normal, and also in destroying them. While both prenatal and postnatal agencies are, of course, concerned in the production of oral conditions which you are called upon to treat, I am inclined to give the former the greater potency. The laws of heredity determine contour and structure and natural characteristics. Habits, on the other hand, are acquired, although tendencies to certain kinds may be predetermined by an inherited faulty mental make-up. A habit spasm, for example, is an evidence of some peripheral physical defect; but it also is found only in those with an inherited neuropathic constitution. Again, habits are readily acquired by nervous individuals and neurasthenics.

Our first thought in the treatment of habits should be to ascertain whether we have a mentally normal individual or an abnormal one to deal with. Speaking broadly, feeblemindedness in a given case may

*Read by invitation at the Third Annual Meeting of the Eastern Association of Graduates of the Angle School of Orthodontia, held at the New York Academy of Medicine, April 27, 1912.

be recognized by the Binet test; dementia præcox by the presence of negativism, stereotypy, mannerisms, etc.; the neuropath by his nervous constitution, faulty heredity, and the nature of his habit which is usually a spasmodic tic; while a very pronounced mental defect, such as we find in idiocy and imbecility, is determinable by simple tests and observation. The jaw condition, which the orthodontist is called upon to treat, and the pernicious habit, which occasionally interferes with his work, may both be looked upon as variations from the normal.

A knowledge of psychiatry, *i.e.* pathological psychology, is of great help to the physician and student in the understanding of the problems of normal psychology; and both are helpful in the analysis of habits.

Recently, in association with a medical confrère, I have been interested in a study of the significance of habit movements in mental defectives.* In these cases the psychic element naturally plays a less important role than in the normal individual. We pursued our investigations in our own service on Randall's Island and found there that a very large number of uneducable idiots and imbeciles had certain peculiar habit movements which were persistent in type. After a careful analysis of these movements it occurred to me that they all bore some relation to or suggested a sexual libido. They were all referable to certain regions of the body corresponding to what Freud has designated "erogenous zones," and they were of the pleasurable sort, as forced interruptions of the habit movements were resented by the patient, at times even with violence. Out of 600 idiots and imbeciles examined by us, 201 exhibited autoerogenous movements and acts. The erogenous zones to which the habit movements studied could be referred were, in the order of their frequency, the face, the pelvis, and the hand. One hundred and twenty-three, or more than three-fifths of the 201 cases were referable to the face and head zone. These were classified into pleasure suckers (of the fingers, rags, tongue, or lips), with the enormous number of 75; biters of the hand, tongue, or lips, 14; strokers and rubbers of the eyes, 13; strokers of their own or other faces, 13; pounders of the face and head, 6; and aural inserters of fingers or of foreign substances, 2. The autoerogenous movements were carried on continuously for long periods of time, *i.e.* they were habit movements. For various reasons, unnecessary to mention here, we concluded that the significance of the autoerogenous habit movements and certain apparently senseless acts of uneducable mental defectives are irrevocably bound up with a defective and perverted sexuality of infancy and childhood. Our views parallel those of Freud in sex genesis for the normal child as laid down in his "Three Contributions to the Sexual Theory." Our discovery has, to my mind, more than a biological and academic interest. It may help in the recognition of very young cases of mental defect. It may help to explain also certain habits and conditions which have been hitherto impossible of control. In a large orphan asylum assembly room we were able by observation alone of about 200 supposedly normal children to select out three cases of mental defect on account of their autoerogenous habit movements displayed. We proved up the cases subsequently by examination and inquiry of the attendant, and were not wrong in any case. The direct application of these remarks to the subject in hand might not occur except in mentally defective cases.

Let us now glance for a moment at certain simple facts in normal psychology in relation to habit. The formation of a habit, psychologically speaking, depends on two things: a sensorimotor connection between stimulus and response and a connection between stimuli. In other words, or to illustrate: let us say that certain sensory impressions are carried from the oral cavity, *i.e.* the periphery, to the sensory nuclei of the brain. They are there discharged into motor cells which return an impulse to the muscles for the production of voluntary movement. A sensation of the movement is also returned to consciousness. If the same sensorimotor process is repeated indefinitely, a more or less permanent connection arises, consciousness gives little or no further heed, and the motor response to the given stimulus becomes automatic. The initiation of the movement only is voluntary, and the sensation of the movement after a permanent connection has been made is sufficient to set off successive discharges, and the act is repeated automatically and subconsciously. If it takes the form of a spasmodic tic, the repetition of the movement is expressive of a neuropathic constitution. If it appears to have a sexual significance it may be generated in psychopathic soil. Automatic habits of some sort, however, are being continually formed in health, especially in childhood. The kind of habits formed is one of the problems of education which consists mainly in the "learning to make certain responses to certain stimuli, and inhibiting others." The ability to grasp the significance of the motor element or reaction to given stimuli enables us to see the value of special training. If special training along any lines can be accomplished in a given case, hope may be held out that other special or even general training may be possible in that case. The present tendency is to interpret in terms of motor adjustments.

The psychology of the child is one of the live topics of the day; and the importance of the motor element in mental life has been steadily gaining in recognition. Those who are content to ignore the actual brain conditions, however, the pathology of mental defectives, are naturally more optimistic of curing their abnormal manifestations than those of us who are brought much into actual contact with them and are familiar practically with these conditions and are unwilling to ignore them. The idiot, speaking broadly, is teachable only in a very limited degree. The cure of habit in those cases is practically impossible on account of the mental deficiencies of attention, memory, etc.

The effect of treatment of habit must always be commensurate in degree with the intelligence of the individual and the strength of the will. It represents for the normal child an adjustment to new conditions. Treatment of habits in the supposedly mentally normal child should be general and special. After all local causes which might give rise to abnormal sensory stimuli have been removed, the general health of the patient must be looked after in every particular and brought well up to par. Faulty conditions of life in the home and school and at play may have to be corrected. The faculty of attention and the will may have to be especially trained. The play instinct should be encouraged, and the social instincts also. Mild punishments for the habit itself may be instituted when there is no mental defect;

*Clark and Atwood: "A Study of the Significance of Habit Movements in Mental Defectives," *Journal Am. Med. Assn.*, March 23, 1912.

and also a system of rewards for well doing. Punishment not only brings the automatic habit into consciousness; it also exercises a restraining influence on repetition. A person is less likely to repeat an act attended by unpleasant consequences than he is to repeat one from which he derives a reward. That form of treatment, however, which should have a great influence in the breaking up of faulty habits, both mental and physical, is substitution. The human motor apparatus throughout is capable of adjustment in an indefinite variety of ways, and the nerve centers in a normal individual enable him to acquire power to make these adjustments. Therefore, unless there is really some mental defect or maldevelopment in a given case, there should be an ability to readjustment to a different series of motor acts if we can get the cooperation of the patient. A frequent repetition of substitution acts is, of course, required to bring about a new habit which should be of a corrective nature. The new corrective habit should be simple and if possible pleasurable and not embarrassing. If necessary it may be imitative. Possibly the origin of the faulty habit in the first instance may have been from imitation. If so, contact with the person whose fault was imitated should, of course, be further prevented. This is very important. Imitation in the child is one of the strongest factors in his mental make-up, and even with the grown-up, example is apt to be stronger than precept. The interest of the child must first be aroused, then the faculty of association, and lastly the memory.

If normal children are forced to do as they should for a sufficient length of time, without arousing too much antagonism on their part, the tendency to act in the enforced way becomes stronger than to act in any other way. Though the acts at first are not agreeable the children ultimately take pleasure in doing what they have developed a tendency to do. As one writer has expressed it: "A habit is a tendency to do a certain thing under certain conditions, hence a change in the conditions giving rise to a habit will often change the habit."

The abnormal physical defects which occur in some backward children, that give rise at times to habits, are not always easy of discovery. An apparent lack of the faculty of attention, for example, may be found to be due to defective hearing. A facial spasm may be associated with adenoids, eyestrain, phimosis, or oxyurides. An apparent backwardness may be augmented by errors of diet or faulty hygiene. Very naughty or very troublesome children are not usually entirely normal. They should be carefully studied, and receive special daily attention and treatment. Finger and thumb sucking can be successfully treated in infants only by mechanical restraint. Nail biting is most helped by keeping the nails cut very short. Tic or habit spasm is a not uncommon disorder in late childhood. It is an evidence, as previously stated, of neuropathic heredity, the exciting cause being a deterioration in general health or some local irritation. It may arise from a trick or habit or from imitation. The cause should be sought and removed. Arsenic and belladonna may be used. In cases of tic also the voluntary repetition of the same movement slowly, for long periods of time, is sometimes helpful. Reeducation and attention to the health are often of greater assistance in the treatment of most habits than psychotherapy. Practising a new habit in front of a mirror may be helpful. If the patient is intelligent and old enough to understand he may be shown pictures and models of perfect jaws and teeth and contrasting models of such as would be produced if the habit were persisted in. Those photographs which I have seen of models by members of your society, are beautiful as models but certainly terrifying as examples. The understanding of one situation makes it easier to grasp others. The long time required to learn a new order (*i.e.* a change of habit), says one observer, depends rather on indisposition than on inability. In mental defectives the attention may be obtained by the employment of music, especially of rhythmic music. Active manual employment in the daytime and watchful control at night are safe devices in these cases.

In conclusion, an undesirable habit cannot be inhibited any more than an undesirable disposition, but if a patient can be induced voluntarily to substitute desirable responses for the undesnrable, a new habit may become automatic after a sufficient number of repetitions. A voluntary surrender of the will, however, is not only highly desirable, but apparently absolutely necessary in order to gain the ascendency. The tendency is ever to fall back to the old adjustment. The old sensorimotor paths are open and a very few impulses only are needed to make them as permeable as ever. This may be a more gloomy view of the situation than the facts warrant, but it is based on what would seem to be unassailable biological and psychological lines. As to the physical treatment of faulty oral habits, by mechanical devices, etc., no doubt your own ingenuity will discover the proper correctives. These will not succeed in mental defectives as a rule. And in the presence of actual nervous or mental complications, I would inject a word of caution, not to meddle except under the intelligent direction of some one who thoroughly understands the nervous system.

14 East Sixtieth Street.

A PRELIMINARY REPORT ON NEOSALVARSAN, WITH PARTICULAR REFERENCE TO ITS EMPLOYMENT AS AN INTRAMUSCULAR INJECTION.

By ABR. L. WOLBARST, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON, CENTRAL ISLIP STATE HOSPITAL; VISITING GENITOURINARY SURGEON, PEOPLE'S HOSPITAL, WEST SIDE GERMAN DISPENSARY AND BETH ISRAEL HOSPITAL DISPENSARY, ETC.

It is two years since the first experimental work was begun on Ehrlich's salvarsan. During this period many hundreds of thousands of injections have been given throughout the world, the results of which may be learned by a perusal of the copious literature on the subject. My personal experience with this remedy is based on some three hundred intravenous injections and about one hundred injections given intramuscularly by the method of Alt. Since October, 1910, I have used salvarsan exclusively in the treatment of syphilis, and my clinical results have been, without a single exception, far superior, or at least equal to those obtained previously with the use of continuous injections of mercury salicylate or bichloride and the iodides. My records show a goodly number of cases of syphilis in various stages, treated with one intramuscular injection of salvarsan (Alt method), late in 1910 or early in 1911, that have not only remained clinically well all this time, but have given a negative seroreaction after repeated trials.

In not a single instance have I been unable to control the clinical manifestations of the disease with salvarsan, as is sometimes the case with mercury and iodides. For the past year I have employed the intravenous method exclusively, rather than the intramuscular method, except in a few cases, because of the ease with which it can be borne by the patient. I am quite convinced, however, that the results are not as lasting as with the intramuscular method. I believe that one intramuscular injection has the therapeutic value of at least three and possibly more intravenous injections. This view is also held by other observers and by Professor Ehrlich, too, who stated to me but a few weeks ago in his laboratory that salvarsan is essentially an intramuscular treatment and that the intravenous method must eventually give way to the intramuscular, if some painless method can be devised. He also believes that neosalvarsan is a step in this direction, as it is more easily borne by the patient and causes far less reaction in the average case when given intravenously.

Neosalvarsan is the name given to the newer and better salvarsan, the laboratory number of which, 914, indicates the tenacity and fixity of purpose predominating in the Frankfort institute. I had the pleasure of receiving a liberal supply of the new preparation early in April, and in the period intervening I have given 40 injections to 30 patients; of this number 17 injections were given intravenously and 23 intramuscularly. The time that has elapsed is manifestly too short for any positive conclusions; consequently this paper must be accepted as a preliminary report, to be followed by further studies later on.

Chemically, neosalvarsan is a "condensation of formaldehydesulfoxyl acid sodium with salvarsan." That is, it is a formaldehyde sodic sulphoxylate of dioxydiamidoarsenobenzol (salvarsan). It has this reaction: $R — NH_2 + HO — CH_2OSONa = R — NH — CH_2OSO — Na + H_2O$. It is a fine yellow powder, resembling salvarsan, but somewhat more yellowish in color and turning reddish on exposure to the air. The peculiar odor of salvarsan when dissolved in water is present, but to a far less degree. It dissolves readily in water at room temperature, the particles assuming a distinct Brownian movement. I have noticed that when the entire tube content is thrown into the water at once a slight precipitate is formed which sinks to the bottom of the mortar and the water remains but slightly or not at all colored; but when the water is stirred with a rod, the precipitate disappears and the water becomes citron yellow in color. On the other hand, if the powder is slowly deposited into the water by tapping the tube with the finger tip, a perfect solution is at once obtained and the water assumes the yellow color without stirring. The solution is neutral in reaction. This is claimed to be one of its most important features, as it eliminates the use of sodium hydroxide for alkalinizing purposes. I found, on several occasions, that the solution gave a faint acid reaction to litmus paper. In its administration nothing is required but sterile fresh distilled water. Saline solution should never be used with it—firstly, because it is entirely unnecessary, and also because it makes the solution turbid and may bring on toxic symptoms, which do not occur when distilled water alone is used.

The powder is contained in ampoules like those containing salvarsan. The exact dosage has not yet been fully determined, but Ehrlich states that larger doses than salvarsan should be used, in the proportion of 3 to 2. In efficiency, therefore, 0.9 gm. neosalvarsan is the equivalent of 0.6 gm. salvarsan. Neither has it yet been determined whether neosalvarsan, frequently repeated, will develop cumulative effects. In view, however, of the fact that larger doses can be used, it would appear that neosalvarsan is a safer preparation than salvarsan, particularly in the hands of the inexperienced. In the guinea pig it has been found that the *dosis tolerata* is 0.2 gm., as against 0.08 gm. of salvarsan. In all of my cases I have employed 0.9 gm. in adult males and 0.75 gm. (equivalent to 0.5 gm. salvarsan) in women, with practically no toxic phenomena or severe reaction, except in one or two cases mentioned below.

As to the frequency of treatment, Schreiber, who was the first to use neosalvarsan, recommended in a personal report to Ehrlich that it be given intravenously four times at intervals of two days, but this interval has been increased to four days by Duhot (*Revue Belge d'Urologie et de Dermatosyphiligraphie*, April, 1912), who believes that total elimination of the drug is not complete until four days have elapsed. I have given it at intervals of two days without any evidences of toxic reaction.

Ehrlich still insists that the water used for dissolving the neosalvarsan must be freshly distilled. In conversation with him recently he laid great stress on this point, declaring that endotoxins are developed in distilled water that is not fresh, which are the causative factor in the development of the toxic phenomena that have been observed in the use of salvarsan. The water should be distilled, sterilized and cooled to room temperature.

The method of administration of neosalvarsan is the same as that of salvarsan, with one exception. Schreiber and Duhot both recommend that not more than 120 c.c. water be used with 0.9 gm. neosalvarsan; that is, 20 c.c. water for 0.15 gm. neosalvarsan. They believe that the more concentrated the solution, the more effective it is. With salvarsan between 200 and 300 c.c. are used.

In my intravenous injections I dissolve the powder in a mortar containing 30 c.c. distilled water at room temperature. This gives a perfectly clear yellow solution. It is filtered (as a matter of precaution) and poured into the flask of the apparatus. Then we add warm distilled water (temperature slightly over 100 deg. F.), also filtered, up to 120 c.c. The fluid is injected into the vein as with salvarsan. I still adhere to my rule to keep patients in bed for at least ten or twelve hours after the injection.

The reaction after an intravenous injection of neosalvarsan is usually nil or nearly so. In my 17 injections I have not had a single instance in which the temperature rose above 100.5 deg., and in most cases it remained below 100 deg. In one instance (a case of tabes with a Wassermann + + + +) vomiting occurred immediately after the injection. For at least four hours preceding and following an injection it is well to interdict all food, as this may bring on vomiting and severe reaction. This is true with salvarsan also. A few of the patients complained of a burning sensation at the point of insertion of the needle, much more frequently than with salvarsan, and I have observed that an escape of a few drops of solution into the tissues causes much more pain than with salvarsan, but it passes off within an hour or two, while it may last for several days with salvarsan. I have never observed the yellow and blue discoloration of the skin which

is sometimes seen when the salvarsan solution leaks into the surrounding tissues. A few patients complained of a slight numbness in the arm and shoulder during and after the injection; this soon passed off, however. Apparently the neosalvarsan solution is absorbed much more quickly in the tissues than the salvarsan solution.

When in Frankfort recently, Professor Ehrlich declared that the best results would be obtained with neosalvarsan or salvarsan when some painless intramuscular method was devised. He believes strongly, to quote his own words, that "salvarsan is essentially an intramuscular injection," and he suggested that it would be well to experiment along this line with the neosalvarsan he had previously sent me. I have accordingly carried on a series of experiments with this object in mind, which I desire to embody in this preliminary report, in the hope that others may take up the subject and carry it to a successful termination.

I began by dissolving the powder in 20 c.c. distilled water, and injected 10 c.c. into each buttock. The pain caused by this injection was so intense that I used it on but three patients. These patients complained of the pain and induration for several weeks. The clinical result, however, was excellent.

In the second series the powder was suspended in 10 per cent. iodipin solution. In these cases, 6, 8 and 10 c.c. iodipin solution was used, respectively, with 0.9 gm. neosalvarsan. The pain was found to be much less severe than in the first series, but the induration and sensitiveness were still very marked. It was then thought that possibly the distilled water solution could be made less painful by the addition of a local anesthetic. Accordingly, in the following series, we injected 0.45 gm. neosalvarsan suspended in 3 c.c. iodipin solution into one buttock, and in the other, for comparison, we injected simultaneously the same quantity dissolved in 1 c.c. of a 1 per cent. solution of beta eucain in distilled water. The latter was much more painful than the iodipin suspension, and had to be given up.

In the next series we suspended the powder in glycerin, with very encouraging result; 0.45 gm. powder was suspended in 1 c.c. glycerin (c.p.) and injected into the buttock. The pain and induration were very slight as compared with anything that had been used previously; by way of comparison with the iodipin suspension, we suspended a similar amount of powder in the same amount of iodipin solution and injected it simultaneously into the other buttock. This was done in four cases, and it was found that the glycerin suspension was much less painful than the iodipin.

In the belief, however, that a clear solution might be more easily absorbed and less painful than this suspension, we added a few drops of water to the glycerin suspension. This dissolved both the glycerin and the powder, but the pain of the injection was increased. Then we dissolved the suspension in a few drops of 1 per cent. beta eucain solution and we found that we had at last an injection that was quite painless.

Finally it was suggested the injection could be made even less painful by dividing the dose into four parts and making four punctures instead of two. This would give us a smaller quantity for each puncture, with greater opportunity for absorption and lesser possibility of induration. We consequently suspended 0.9 gm. powder in 4 c.c. glycerin and then added a few drops of 1 per cent. beta eucain solution in distilled water. In a few instances I have used 1 per cent. alypin with equally good result. Eleven intramuscular injections have thus far been given in this way, most of them in my service at the West Side German Dispensary. A few have been given in my private practice. In every instance the patients have been more than satisfied, there being practically no pain, except a slight stiffness for a few hours, noticed mostly when the patient stooped or sat down. It is quite likely that even this sense of tenderness can be obviated by injecting into the lumbar muscles as suggested by Meltzer. We have not yet tried this method. In one case a moderate induration was observed on the second day at the site of one of the punctures, but this was not painful, nor did it cause any inconvenience. Taken altogether, this intramuscular injection is by far the most satisfactory I have thus far encountered and is worthy of a more serious trial.

In all of these cases the clinical result has been excellent. Primary and secondary lesions have responded beautifully, though not so rapidly, at times, as with the intravenous injection. The time is too short to speak of permanent results or of the effect on the sero-reaction, but it must be evident that we have here a very potent therapeutic agent that can be administered in the office, without the necessity of the patient's going to bed. This itself is a very decided advantage in its favor over the intravenous method, apart from its greater effectiveness.

In detail, these cases may be classified as follows:

Series 1. 3 *cases. Neosalvarsan dissolved in* 20 *c.c. distilled water;* 10 *c.c. injected into each buttock.*

Observation. Pain intense immediately after the injection and lasting from one to three weeks. Induration marked. No necrosis or abscess formation. Skin hot and tender. In one case (cerebral syphilis) the patient vomited after the injection. Curiously enough, this patient had previously received three salvarsan injections suspended in iodipin solution without any vomiting at any time. Clinical result in all three cases, excellent.

Series 2. 3 *cases. Neosalvarsan suspended in* 10 *per cent. iodipin suspension*:

Observation. Case 1, 0.9 gm., suspended in 8 c.c., iodipin solution. 4 c.c. injected in each buttock. No pain at time of injection, but moderate pain next day, which lasted several days. Slight induration. Clinical result good. Case 2, 0.9 gm., suspended in 6 c.c., iodipin. 3 c.c. in each buttock. Moderate pain, lasting three days. Moderate induration. Clinical result excellent. Case 3, 0.9 gm., suspended in 10 c.c., iodipin. 5 c.c. injected in each buttock. Moderate pain and duration lasting five days. Clinical result good.

Series 3. 2 *cases.* 0.45 *gm., suspended in* 3 *c.c. iodipin, injected in one buttock; in the other,* 0.45 *gm., dissolved in* 1 *c.c.* 1 *per cent. beta eucain solution in distilled water.*

Observation. The beta eucain watery solution was far more painful than the iodipin. One patient remarked that the induration felt like a tennis ball. Induration marked on both sides and in both cases. Pain lasted five days. Clinical result, good.

Series 4. 4 *cases.* 0.45 *gm., suspended in* 3 *c.c. iodipin and injected in one buttock; in the other,* 0.55 *gm., suspended in* 1 *c.c. glycerin* (*c.p.*).

Observation. Pain and induration of the glycerin suspension was much less than the iodipin. Clinical result in every case excellent. Pain noticed only on sitting or stooping.

Series 5. 11 *cases.* 0.9 *gm., suspended in* 4 *c.c.*

glycerin, to which was added a few drops of 1 per cent. beta eucain or alypin solution, dissolving the glycerin.

Observation. Pain and induration reduced to minimum. Most patients have felt almost no pain; some have felt pain on sitting or stooping for a day or two. Induration very slight.

Technique. The powder is mixed in a mortar containing 3 or 4 c.c. glycerin (c.p.); to this is added a few drops of 1 per cent. beta eucain or alypin solution in distilled water. The suspension has now been converted into an almost clear watery solution. The buttocks are painted with iodin, and four spots are located, two in each buttock, into which 1 c.c. of the solution is injected and slight pressure made by the hand. The patient is not confined to bed.

Conclusions. As to neosalvarsan:

1. The clinical results are at least as striking as those of salvarsan.

2. The reaction after treatment is nil or very slight, with correct technique.

3. Larger doses are more readily tolerated than with salvarsan.

4. The neutral reaction of the solution in water obviates the use of sodium hydroxide, thus avoiding the possibility of thrombosis.

5. Leakage of neosalvarsan solution into the tissues seems to be absorbed much more quickly than with salvarsan.

6. Patients feel the inflow of the neosalvarsan solution much more than that of salvarsan, in the form of a sense of burning at the site of the injection.

7. Neosalvarsan has no apparent effect on the eyes, kidneys, heart or lungs.

8. Intravenous injections may be repeated in 2 to 4 days.

As to the intramuscular method:

9. The neutral reaction of neosalvarsan solution lends itself readily to intramuscular medication, which is admittedly more effective than the intravenous.

10. The suspension in glycerin is made almost painless by adding a few drops of 1 per cent beta eucain or alypin solution.

11. The solution of neosalvarsan in distilled water is very painful.

I desire to express my thanks to Drs. Saul Steiner and Joseph Kaufman, of my service, for their assistance and cooperation in this preliminary study.

113 East Nineteenth Street.

BEDBUGS AND BUBONIC PLAGUE.

By JACOLYN VAN VLIET MANNING, M.D.,

BROOKLYN, N. Y.

The fact that the bedbug, *Cimex lectularius*, is an agent of transmission of bubonic plague was not known to the English-speaking world until Nuttall, Quick Professor of Biology in the University of Cambridge, published in the special plague number of the *Journal of Hygiene* a translation of the experiments of D. T. Verjbitski, a Russian engaged in research in the laboratory of the Imperial Institute of Experimental Medicine at St. Petersburg. Verjbitski's results were definite, proving that bedbugs fed on animals dying of plague communicated the plague to guinea pigs for five days afterward; fleas fed on animals dying of plague communicated the plague to other animals for three days. Verjbitski says in his report: "These experiments were conducted with guinea pigs. The plague culture was enhanced in virulence by passing through several guinea pigs. The bugs used were *Cimex lectularius*, which is the usual domestic parasite. The strong irritation occasioned by its bite is caused by the action of the saliva which is injected into the wound. A bug never inflicts but one bite, and does not leave the place until it has filled itself with blood. Its body under these conditions acquires an egg-shaped form. The bedbugs, in series of fifty, were applied to guinea pigs dying of plague, and to an area of skin under the thigh which had previously been shaved. The results definitely proved that the bedbug transmits plague, and that as an agent of such transmission the bedbug is to be more feared than the much dreaded flea of man and animals."

Verjbitski's summary,[1] under sixteen heads, of the results of the sixty recorded experiments is here given: "(1) All bedbugs and fleas which have sucked the blood of animals dying from plague contain plague microbes. (2) Bedbugs and fleas which have sucked the blood of animals suffering from plague contain plague microbes only when the bite is inflicted twelve to twenty-six hours before death, that is during that period when the blood contains plague bacillus. (3) The vitality and virulence of the plague microbe are preserved in these insects. (4) The plague bacillus is found in bugs which are not starved, one to seven days; in bugs previously starved four months, they are found eight to nine days. (5) The number of plague bacilli increases the first few days. (6) The feces of the infected bug or flea contain virulent plague bacilli as long as they persist in the alimentary canal of the insect. (8) The more virulent the culture with which is inoculated the first animal on which the bug was fed, the more certainly the infection was conveyed by bites. (9) The local inflammatory reaction in animals which died from plague occasioned by bites of infected insects was very slight or absent. In the latter case one could only locate it by the situation of the primary bubo. (10) Infected bugs communicated disease to healthy animals five days; fleas, three days. (11) Not more than two animals were infected from the same bug. (12) Crushing of infected bugs in situ in process of biting, occasioned, in the majority of cases, the infection of healthy animals. (13) Injury to the skin occasioned by the bite of the bug or flea offers a channel through which the plague bacillus can easily enter the body and occasion deaths from plague. (14) Crushed infected bugs and their feces can infect small punctures of the skin caused by bites for a short time after infliction of bites. (15) On linen soiled by crushed bedbugs (or fleas) or their infected feces the plague bacillus can under favorable conditions remain alive and virulent for five months. (16) Chemical disinfectants do not in the ordinary course of application kill the plague bacillus in the infected bug or flea.

"In crushed infected bugs the plague bacillus preserved its morphological characteristics during all the time it was found in the bodies of bugs. In the midst of a great mass of well preserved blood corpuscles could be seen an enormous quantity of plague bacilli in almost pure culture. Experiment XLII: The inner surface of the hind leg in six guinea pigs was scratched three times with a fine needle and the crushed bug was rubbed over the scarification; all of the six pigs died of plague in forty-seven to sixty-nine hours. Pure cultures of

plague bacilli were obtained from the following sources: (1) The crushed infected bugs on bits of linen—(a) dried thirty-five days at room temperature (b) 130 days in damp environment at 4 to 5° C., (c) exposed during eight days to direct sunlight, and (d) frozen ten days at 5° C. to 18° C.; and (2) from the feces of bugs which had been allowed to dry on linen at room temperature for ten days. These were all verified by the inoculation of guinea pigs. From the results we must conclude that clothing and bedclothes which are soiled with material from infected insects, obtained either by crushing them or from their feces, can serve during a long time as a source of infection. The clothing of people who live in dirty, unhygienic surroundings is generally covered with spots from crushed bugs and their feces. Formalin vapor is a poor insecticide, especially for bugs."

The following description of the bedbug is quoted from the bulletin, *The Bedbug,* of the U. S. Entomological Bureau:

"The bedbug has accompanied man wherever he has gone. Vessels are almost sure to be infested with it. It is not limited by cold. The presence of the bedbug in a house is not necessarily an indication of neglect, for, little as the idea may be relished, this insect may often gain access in spite of all reasonable precautions. It is apt to get into the trunks and satchels of travelers. It migrates from one house to another, sometimes for a period of several months, gaining entrance daily. Migration is apt to take place if the inhabitants of an infested house leave it. With the failure of their usual source of food the bedbugs pass along walls, water pipes and gutters, and gain entrance to adjoining houses. The bedbug is thoroughly nocturnal in habits and displays wariness, or intelligence, in its efforts at concealment during the day. It usually leaves the bed at the approach of daylight, to go into concealment in cracks in the bedstead, or behind wainscoting, or under loose wall-paper, manifesting its gregarious habit by collecting in masses. The inherited experience of many centuries of companionship with man has resulted in a knowledge of the habits of the human animal, and a facility of concealment, particularly as evidenced by its abandoning beds and often going to distant quarters for protection and hiding during daylight. The bedbug belongs to the order Hemiptera, characterized by possessing a piercing and sucking beak. The bedbug, though normally feeding on human blood, is able to get more or less sustenance from the juices of moistened wood, or the moisture in the accumulations of dust, etc., in crevices in flooring. The biting organs of the bedbug consist of a heavy underlip within which lie four thread-like, hard filaments which glide over each other with an alternating motion and pierce the flesh. The blood is drawn up through the beak, which is closely applied to the point of puncture, and the alternating motion of the setæ in the flesh cause the blood to flow more freely. In common with other insects which attack man these pests may be the transmitters of contagious (?) diseases. The bite of the bedbug is poisonous to some individuals. To such the presence of the bugs is sufficient to cause the greatest uneasiness. With others, however, the presence of the bugs may not be recognized at all, and except for the occasional staining of the linen by a crushed individual their presence might be entirely overlooked. The bedbug is known to be able to survive for long periods without food. In unoccupied houses it can undoubtedly undergo fasts of extreme length. Individuals obtained from eggs have been kept in sealed vials in this office for several months, remaining active, in spite of the fact that they had never taken any nourishment whatever. Bedbugs are said to lay several batches of eggs during the season and are extremely prolific. The eggs are white oval objects and are laid in batches of one-half dozen to fifty in cracks and crevices where the bugs go for concealment. The eggs hatch in a week or ten days. Breeding experiments conducted at this office indicate seven weeks as the period from egg to adult insect."[2]

Are bedbugs a common factor in American homes? In each of the following instances I have observed bedbugs in large numbers: (1) Having had occasion to trace the source from which bedbugs were found on a white infant in a North Carolina home, I investigated the sleeping quarters of the colored cook and maid; the bed-frame under the mattress in each bed was a crawling, seething mass of bedbugs. (2) Tracing to their source the bedbugs which appeared in a scrupulously kept medical ward of Cook County Hospital, Chicago, I found the bed of the kitchen man, which he had previously made and "bugged" himself, alive with bedbugs. The bed-frame, drawn out on the concrete floor, was swabbed with alcohol and then fired, when the bedbugs literally boiled out of every joint in the iron. (3) Attending at night an obstetric case in the Chicago Ghetto while externe at the Chicago Lying-in Dispensary, I found hundreds of these crawlers descending the board partition which formed one side of the room. Called to the apartment of an unknown woman at night, I found her bedclothing swarming with bedbugs. Composing myself to sleep in a richly upholstered reclining chair on a train in the Southwest in late October I was at once attacked by bedbugs in such numbers that all portions of the body felt as if scorched with flame. (5) In a previous paper[3] I have recorded witnessing the migration of a bedbug from a sick man, across the aisle of a coach in the Hudson tube, to the skirts of a party of ladies; this migration took place in February, showing how little season affects the roaming of this pest, as well as its voluntary migration from sick to well, as a possible means of transferring disease.

Observation demonstrates that constant distribution of the bedbug among members of the various social classes takes place: the physician returns from the slum case and the lawyer from the court where bedbugs swarm; the maid takes her half-day in a tenement home, the daily paper is distributed by a tenement dweller, the hand laundry often returns from a tenement district; the vacation is spent in unfumigated summer camps, and the traveler's bag or trunk is a usual hiding place for cimex; men, women, and children of all social classes come in close contact in railroad stations, transit-lines, theaters, schools, moving picture entertainments, summer amusements, and public inns. The invasion of the American home is more successfully accomplished by the gentle art of concealment practised by the retiring but ubiquitous bedbug. To the prophylaxian Verjbitski's demonstration that begbugs transmit blood-borne diseases is the most revolutionary discovery made since Pasteur announced the etiology of anthrax. This illuminating thesis lightens the path along which science has floundered in search of the common mode of transmission of acute epidemic disease. It

would appear that any disease whose germ or virus is liberated in the blood during any stage of the attack, may be transmitted by the ubiquitous bedbug.

The prophylaxis of bubonic plague and possibly of epidemic polimyelitis, therefore, must first secure the extermination of the bedbug. The bedbug must be excluded by destruction from all dwellings, business districts, public halls and utilities, free dispensaries and night shelters, hospitals, and churches, rolling stock, and passenger ships. An annual spring extermination of the bedbug will result as well in the destruction of all cockroaches, spiders, ants, house centipedes, and hibernating adult flies and mosquitos. An annual renovation to be effective must include not the bedchambers of a house only, but every room in the house; not a single flat in an apartment house, but every floor including the basement and restaurant; not one house in a tenement row, but the entire block.

The methods to be employed are (1) general, including fumigation by hydrocyanic acid gas or brimstone, or destruction by fire; (2) local, including the application of various volatile or other poisons, or of boiling water.

Hydrocyanic acid gas method: The immediate and complete sterilization of a building and all its contents, with the total destruction of all germs, parasites, and vermin on the premises can be accomplished by fumigation with hydrocyanic acid gas. The gas penetrates every aperture, and leaves behind it the death of every organism; the dust will be undisturbed but innocuous; no cockroach or waterbug will be seen about the plumbing; no bedbug, moth, mosquito, or housefly will emerge from any crevice or drapery. Fumigation by this method is so exact that it should be in common use at least once a year; its immediate effectiveness recommends it for use in all aggravated and intractably insect-ridden houses. The method, however, is both expensive for individual use, and dangerous when employed unintelligently. Individual experimental use of the hydrocyanic acid gas method is not advocated. It should be a part of the equipment of the municipality which is placed at the call of the individual citizen, as is fire protection, and should be compulsory in all buildings enumerated above during the months of spring. Annual compulsory municipal fumigation can be accomplished by municipal ownership of equipment and sufficient accessory apparatus in the way of tents, etc., to house for twenty-four hours the inhabitants of one city block, notification to be given one week in advance. The hydrocyanic acid gas method of fumigation of houses is given in detail by L. O. Howard, Chief of the United States Bureau of Entomology, in *Circular Bulletin* 46, revised edition.[4] In response to a letter of inquiry regarding the use of the hydrocyanic gas in tenements, Dr. Howard replied: "In order to be effective and safe in East Side tenements, fumigation with hydrocyanic gas should only be carried on in the central one of three vacated buildings. I doubt very much whether one could get the people out of an entire block in that congested quarter, or even out of one building." Yet it is in the slums of our great cities in which pestilence breeds and from which it spreads. The first great epidemic of poliomyelitis of 2,500 known cases occurred in New York City in 1907, and only a cripple census would reveal how many cases occurred which were unnumbered in that report. It is in these slums that bedbugs abound.

Sulphur fumigation: It is sometimes very desirable in the eradication of parasites to fumigate a room at a time, or to fumigate several rooms successively. Summer camps and seaside cottages may be infected with bugs and should be fumigated before occupancy. A room or a relatively small house can be satisfactorily treated by sulphur fumigation. Sulphur will bleach books or draperies and all metal will tarnish. The sulphur candle is convenient for use. Use one candle for a closet of ordinary size and for a room which can be sealed use one pound of sulphur candles to each thousand cubic feet of air space. It will not be necessary to seal a vacant frame building, but it will be necessary to increase the amount of sulphur to 2 pounds for each 1,000 cubic feet of air space and close the building for treatment at least twenty-four hours. The sulphur should be placed in a good sized receptacle such as a coal-hod, which should be placed in a pan of water, so that there may be no overflow of the burning mass to start a conflagration. Close all windows, registers, ventilators, and large apertures, but do not paste up broad cracks with strips of paper, as by that means may be preserved alive the vermin you wish to destroy. Ascertain that the sulphur is well fired and burning, and close up the room or cottage for twenty-four hours. The premises should be well aired for a day succeeding the fumigation before occupancy.

Destruction by fire: When small structures of moderate value, such as chicken coops, outside closets, and summer camps, have become infested with bedbugs, the best prophylaxis is incineration. A great deal of old household articles stowed about the country house should help to feed the fire. Old and unused bedsteads of wood, folding beds, picture frames, and trunks are especially liable to be infested. The rubbish in attics becomes infested from begbugs brought to the chimneys by swallows and bats, and these parasites can no longer be considered harmless. Fire can be used effectively in freeing an iron bedstead which is thoroughly infested with bugs; bugs sometimes take complete possession of a neglected bed in an institution, and will be found to have invaded any joint or crevice in the gas pipe of which it is often constructed. The bed must be removed to a concrete floor, or out of doors; alcohol poured about all crevices and joints and immediately fired, will destroy every bug and all the eggs; the wire springs can be fired by passing a burning newspaper torch below them.

Local application: The application of corrosive sublimate, the petroleum oils, and the various insecticides is not advocated for the reason that, while any of these agents will kill a certain number of bugs, they will at the same time drive others to a different bed or another room, and the fight must be soon renewed; also, the treatment of a few pieces of furniture or a portion of a house is mere temporizing, for owing to the secretive habits of the bedbug a small number only will be destroyed. Water, poured from the teakettle in which it is still boiling, will kill all bugs and eggs on the area to which it is applied. Quicksilver, beaten to an emulsion with egg albumin, is very destructive, as the bedbugs will feed on the fresh albumen and die.

This article is drawn from material acquired in the study of the epidemic transmission of acute poliomyelitis; at a certain stage of research I found it compulsory to investigate the habits of the bedbug, which I now consider to be a probable factor in the spread of infantile paralysis, as it has been proved to be in the case of bubonic plague. There-

fore, all measures which are advocated in this article for the prophylaxis of a foe which has not yet touched the North Atlantic seaboard, may be applicable in the prevention of all diseases whose virus is present in the blood of the host during the acute stage of the disease. Of these measures there is none which would exceed in effectiveness the annual compulsory municipal fumigation of all habitations of man.

THE ERROR OF COLLEGE CRITICISM.

By O. L. MULOT, M.D.,

Brooklyn, N. Y.

In the Medical Record of September 18, 1909, I made a prophecy that less than a year later was fulfilled; the skeleton of our medical educational system was dragged forth from its dark closet and paraded through the daily papers. As a result of this, there were ruffled fur and feathers. Indeed, in some quarters the feeling ran so high that there was serious talk of having the law on the sacrilegious rascals who picked the closet lock and then rattled the dry bones so loudly. It is sincerely to be hoped that a sober second thought and wiser counsel has prevailed and that these, so grossly outraged worthies, will spare themselves the chagrin of seeing the case proven against them. They must not forget that after all, they have only themselves to blame for the conditions upon which specific criticism was exercised.

The Carnegie Foundation report which is the one that has aroused this tempest in a teapot, is neither to be praised nor deplored. That the conditions in some of the schools was well known and that this must sooner or later become common public property, was easily to be foreseen. Within the last few years these conditions have been the subject of study and remedial measures were advocated, but those in control of the schools have obstinately refused to take heed. On the other hand, we cannot congratulate ourselves that this report accomplishes much, if any good. While it certainly lost for the severely criticised schools a few students, strange to say it also attracted others; particularly such, who having failed to get through in one school, and still determined to get through, will go to the schools where they are led to believe that it would be easier and cheaper. A bad advertisement, it is true, but still one that equalized loss and gain. Thus, those entrenched in the control of such schools, snap their fingers at the report and its author, turn a deaf ear to friendly counsel and obstinately stick to the old rut.

The whole report on medical schools merits no serious consideration. The idea of a man who never studied medicine and therefore does not understand it, criticising the teaching of that science is incongruous and ridiculous. Imagine a physician criticising a divinity or a law school; his criticism would be treated as the work of a humorist and why should a layman's criticism of medical schools be more seriously considered? Nowhere in that report have I been able to find one suggestion by which a specific school was shown how it could improve its condition. It does not contain one line of constructive criticism; it is all along destructive lines. That is the easiest and cheapest kind, for it requires no ability to make and it in fact is good evidence of incompetence.

All criticism of medical schools, be it from a single individual or from a committee of some organization or even backed by the influence of philanthropic multimillionaire, is futile and misdirected, and the reason for this statement will be made clear further on. Furthermore, it is to be deplored that in the Carnegie Foundation report so much stress is laid upon the financial resources of the schools. We all appreciate the advantages that money can give a school, but money in medical schools, as in every other thing in life, is not every thing or the whole thing. Naturally there will be a difference between the criticism of the layman and that of the practical physician, who has had a teaching experience. Not one of the criticised medical schools has found in that report specific recommendations to fit their needs. It is clear to any one, that a school that has a total class of sixty or eighty, does not need such a voluminous equipment as does a school that has a total class of four hundred. By a judicious time arrangement, a smaller equipment can be made to serve for the instruction of the various grades, also for the instruction of various subjects, and where the classes are small it is not at all necessary to have different complete outfits and separate rooms for each subject. What I have here hinted at is too evident to require further elucidation. The object of medical educaton is not to train every student to be an individual and independent researcher, but it is to educate and train them to be competent and safe men in the sick room; for this is what at least 95 per cent. must be. If the first were the result of all medical education, it would indeed be a deplorable one, for then it might easily happen that in the scientific ardor, the patient would be only a secondary consideration. Nor is scientific research suited, or rather not every man who enters a medical school is suited to scientific research, and it does not follow that because a man is unsuited to research work he will not make a good physician, nor does it follow that a good research worker would make a good physician. That the laboratory worker is often far out of touch with the needs of the practical man is shown by the amount of stuff that comes from the research laboratories that is absolutely valueless to the practitioner, while many of the really practical things that are so badly needed, experience no progress. What some of the schools need much more than elaborate equipment, and which is of far greater importance, is the willingness and capability of the men in charge of the schools, to bring these up to a high standard and make their equipment, meager as it may be, count for all that it is worth. To this end they must fill the teaching staff with progressive, studious men, and preferably actual practicing physicians, not pure theoreticians, for after all only a physician can really appreciate the students' needs and instruct him according to those needs. They must be men who put their heart and soul into the work while they are at it and teach modern medical science, not simply the dregs of medicine. Such men must have pedagogic ability and not instill into the

minds of the students only medical science and facts, but above all, the art to think medically and independently of text books. Let there be no man on the staff who does not completely fill his position; let none hold vainglorious titles with which they puff themselves and use for advertisements, but are totally ignorant of the duties and responsibilities and do not even make a pretense of filling the position. This is a direction in which many of the criticised schools can work out an improvement without increased financial resources and would do much to overcome the handicap of cramped finances.

But as long as appointments and promotions in the teaching staff of our medical schools remain questions of favoritism, just so long will there be incompetent and indifferent teachers, particularly in the minor positions. Not until every position in the medical college, from an assistant in the dispensary to an associate professor, are subject to a competitive examination, free from all favoritism and strictly on its merits, will we have teachers worthy of the name. This is the practice in France; pick up any French medical journal and you can see these competitive examinations announced and they are open to all who can fill the requirements as to length of time in practice, hospital experience, etc. In that country the competitive examinations are not confined to the positions directly connected with the teaching faculty, but all dispensary and hospital positions are subject to it; by hospital positions is not meant the interne staff alone, but the attending physicians and surgeons owe their appointments to having won them in competitive examinations. Surely it is more in keeping with professional dignity to hold a position so won, than to obtain it by political and social wire pulling and the use of other silent but powerful means that only too frequently are used in our country in the getting of hospital appointments. Another commendable thing that this system effects is that the graduate with ambitions knows that he cannot neglect to keep up his anatomy and physiology, etc., for without these he can never hope to succeed in any of the examinations. All the large hospitals are under the control of the faculty; that does not mean that the staff of each hospital are all professors or associate professors; no, they do not make the title quite so common, but the faculty conducts the competitive examinations for the staff positions. Clinics are conducted at such hospitals by the attending physicians and surgeons, and by virtue of the appointment from the faculty such clinics are really under the authority of the faculty. Paris has only one faculty of medicine.

Under such a system we do not see such a spectacle as was recently enacted in a large hospital, when it was announced that the surgeon who placed the largest number of patients in the hospital would be given the choice of the chief surgeonship of any division. This procedure practically eliminated a surgeon of national reputation, whose skill had largely contributed to the success and fame of that hospital.

A word about clinical teaching. In my previous article I pointed out how much of the student's time was wasted in teaching him that which he later on did not use, particularly laboratory work. If the future physicians are to be made good diagnosticians, men who will use every aid that the clinical laboratory and its methods can afford him, besides what is to be learned from correct physical explorations, then the student must see these laboratory aids continually used by his clinical teachers in the hospital and in the dispensary. Unless he sees them actually and regularly used in the practice of his teachers he will consider them superfluous. It does not suffice to send the urine to the laboratory, for if this is done in the section teaching in the dispensary, the student has no means of following up the case and the case may readily be forgotten either by the student or the teacher; the examination should be conducted then and there. Such examination need not occupy a long time and the student may well make it himself, but the teacher in charge must be competent to make it. Recently in conversation with a physician, who holds an important professorship in one of our medical colleges, he remarked that he had no patience with men who needed guinea pigs to establish a diagnosis. A physician who expresses such an opinion has outlived his period of usefulness as a teacher, being medically too far behind the times to be intrusted with the instruction of medical students.

What some of the medical colleges seem to need, quite as much as funds, is a superintendent; a man with some sort of a business head on his shoulders. By stopping small leaks, a smaller pay roll of those performing the menial work connected with the buildings and laboratories on the principle of a day's work for a day's pay, economies could be effected. In the school with which I had the honor to be connected, a very large dispensary, in which everything was free to the patients, was maintained. It was admittedly not an altruistic affair, but run purely for the purpose of supplying teaching material. A conservative estimate of the cost of this is from $7,500 to $9,000 a year. This could easily be made self-supporting by the charge of a nominal fee; the charging of such a fee would reduce somewhat the number of patients, but there was at that particular dispensary, at all times, such a superabundance of material for teaching purposes that a slight reduction would not have mattered. Even if such a nominal charge did no more than make this department self-supporting, such a saving in the eyes of a business man is not to be despised. A teaching institution to be efficient need not be prodigal.

Lately there has been much stress laid upon the advantages of medical schools being a department of some university; aside from the financial aid, I can see no advantage. The future physician's needs in chemical and physiological knowledge differ from what is usually taught in the academic colleges, and nothing that the author of the Carnegie Foundation report has said has caused me to change my opinion about that. In that report, after a specific report on each medical school in the State of New York, he sums up the situation, in which summing up he says: "Of the eleven medical schools now existing in the state, only the bona fide university departments can then expect to survive; outside of New York City, Syracuse University alone has just now a chance. The schools of Albany, Buffalo, and Brooklyn belong to the past. None of the three has even yet entirely emerged from the fee-dividing stage. Syracuse, with a smaller total fee income than any of them, devotes every dollar to the development of the fundamental branches and has fairly earned support from outside." This statement is a little surpris-

ing when compared with the specific report on the Brooklyn school. There is another essential to an efficient medical school, and that even an abundance of money, enthusiasm and sagacity on the part of the teaching staff cannot overcome or get along without. This is an abundance of material for practical anatomy and an abundance of patients for clinical teaching. The layman-author of the Carnegie report, apparently absorbed only with the money strength of the institutions, seems entirely to have lost sight of this most essential requisite while writing the above statement. About the abundance of material in Brooklyn I have personal knowledge. That borough, with over 1,800,000 inhabitants, with its big water front, its vast shipping industries and factories, abounds in material. Albany, with Troy and Cohoes to draw from, should also have ample material; and the same can be reasoned to be the case for Buffalo from the geographical location and census. Very probably the author of the Carnegie report does not appreciate the fact that in the teaching of one very important branch of medical practice the Long Island school excels all the other schools in the State, if not in the country; that branch is obstetrics. That does not call for original research work and an imposing laboratory, but in my humble opinion is very, very important. I believe that if those in charge of the so-severely criticised schools will make an honest effort to bring their institutions up to the highest efficiency with their present resources; if they prove themselves worthy stewards, then the alumni and the local pride will come to their rescue and furnish more abundantly the sinews of war. Laboratories are what are costly, and here money may spell efficiency. They are essential for a good ground work, but for this there need be no prodigality; but even money, in a small city of say twenty, thirty, or even fifty thousand inhabitants, surrounded by only a sparse urban population, cannot supply material for practical work in sufficient abundance and variety. It is the practical experience in the dissecting room, in the dispensary, and at the bedside in the hospital that counts in the making of doctors, and counts very much more than the laboratory.

Right in our medical schools can be found the defect which so generally pervades the whole of our educational system—lack of thoroughness. We strive, and apparently achieve, the big things easily; but it is only training that will make men work out, patiently and methodically, the small detail, and without that detail the big things will not stand the test of careful examination. It is appreciation of attention to detail that has placed the Europeans and their schools in the enviable position these hold.

From a study of the latest reports of the organizations that are interested in bringing about improvements in our medical educational institutions, several things stand out clearly.

First, that we are over-producing doctors.

Second, that we have too many schools.

Third, that many of our schools are deficient.

There is no exception to be registered against this diagnosis, but the remedies advanced to correct these carry little hope of a cure or even lessening the evils.

Against the first, a higher educational standard as a preliminary requirement is urged; but this, after all, would bar only a comparatively small number. Too many are still attracted to medicine as a profession, by the belief that it is a lucrative and easy way of making a living. Let the average earnings of physicians, and the hardships of the life as these really are, stripped of romance, be made known to every youth and you will keep out the many who regard it purely from the financial side. Let this be told by those that are in it, not by the novelist, who embellishes the calling and his hero according to his fancy, but himself is totally ignorant of the heartaches, the bitter disappointments, the sacrifices, and the ingratitude of it all. This, only those that are in medicine can know and appreciate. Do not tell the youth only of the large fees the surgeon sometimes gets, but tell him also of the many, many little fees that he never succeeds in collecting, and these far outtotal the big ones. The percentage actually collected of the total sum earned, the alacrity and cheerfulness with which patients do *not* pay their doctors' bills; tell the truth about these thing to every youth and you will more effectively reduce the number of medical students than can be accomplished by any raising of educational standards. Educational facilities are today within the reach of nearly every one who has the will to grasp them.

The over-abundance of schools, especially of the inefficient kind is not a question that can be so simply solved. While consolidation of schools is lessening the number, and others for want of support or other reason have closed their doors, there still remain too many. The question as to what shall be done with these inefficient ones has been fruitlessly debated. The fact is that nothing can be done; no one has the right to pass death sentence upon them, for the very simple reason that neither an individual or organized critics have the slightest jurisdiction over them, and only the State from which the school received its charter has control. As long as the schools live up to the requirements fixed by the State, just so long can the schools snap their fingers at their critics. Therefore, the State must be the subject of criticism. Force the State to fix the higher standard for medical students' certificates and the colleges will obey the law or forfeit their charter. I do not mean that only those possessed of an academic degree shall be admitted to the study of medicine; that would be a manifest injustice. He who does not possess such a degree should have the privilege of taking an examination, even if such an examination is equivalent in severity to that of a bachelors' degree.

The State is the proper authority to fix the standards of preliminary requirements; it does not however dictate how or where the student gets them, whether he gets them from private tutors or from schools, as long as he can prove that he possesses them. Why then should the State assume a different and dictatorial attitude as to how the doctor gets his qualifications? For it does not accept the diploma from the medical college as a license to practise medicine. Who is responsible for the qualifications of the men licensed to practise medicine? The State, through its board of licensing examiners. The license comes from the State, not from the college. If men inadequately instructed are licensed, the licensing board is to blame, not the college that graduated them. Upon this board rests the final responsibility of the qualifications of the men admitted to practice. Let the board make the examination a practical as well as theoretical one; let it be conducted in the wards of the hos-

pital, in the laboratory, in the manikin and in the dissecting rooms. Then those who pass, to them may safely be entrusted the lives of the community; then the public can disregard where, how, and by whom their doctors were educated.

I, among many others, have wasted time and misdirected energy in the criticism of the medical schools, but I have come to believe it an error. I believe that if the energy of all the critics had been directed into other channels, especially that of persuading the various state boards to conduct more rigid and rational examinations, much more real progress would have been made and without engendering all the bitterness that has marked the whole question. Let criticism and pressure be brought to bear upon the various State licensing boards to make their examinations what these should be, and the whole college question will automatically regulate itself. For the college that has the larger percentage of State boards' failures will soon be shunned by students. That will mean that that school must strive to educate its students to pass the State board examination or close its doors for want of patronage. The State board of examiners can, without dictation and without harassing, determine the quantity and quality of the medical teaching and without helping a layman to pose as the Moses of American medical education.

424 Halsey Street.

ABDOMINAL TUMORS OF TUBERCULOUS ORIGIN.

By ALEX C. WIENER, M.D.,

CHICAGO, ILL.

Of recent years our knowledge of tuberculous infection has been extended in two directions: (1) In establishing the fact that tuberculous toxemia exerts an irritating influence upon tissues, independent of the presence of the bacillus itself or its debris. (2) In the recognition of tuberculin as a diagnostic and therapeutic agency of the greatest value. Robert Koch himself hardly realized the influence which his discovery was destined to have in revealing the etiology of tumors.

Karl Ziehler in his pathbreaking work on "The Toxins of Tuberculosis" has proved beyond a doubt that the chemical substances extracted by dialysis from tubercle bacilli or their debris have the faculty of producing typical tuberculous reactions in organisms which are hypersensitized. This purely chemical derivative of the tubercle bacilli when admixed with the blood and the lymph may produce proliferations of a neoplastic nature which do not betray their tuberculous origin microscopically or through guinea-pig inoculation. The tuberculous toxine irritates both the connective tissue and the functioning cells. Theoretically such proliferation may occur in any organ of the human body. My own observations are confined to the lymphatic and the thyroid glands, the mamma, and the intestinal tract.

Quite a number of observations have been reported in regard to the simultaneous occurrence of tuberculosis, carcinoma, or sarcoma in the same patient and in the same organs. Among the many interesting publications on the subject I will cite only the paper of I. P. Simons, which appeared in the Johns Hopkins Hospital Bulletin for January, 1911, under the title "Sarcoma and Tuberculosis." A postmortem on a 60-year old negress at the St. Louis City Hospital showed a diffuse and tuberculous peritonitis and retroperitoneal sarcomata. In conclusion Simons says: "The chief interest in this case lies in the association of a very rapidly growing, typical, spindle-celled retroperitoneal sarcoma with a very virulent tuberculous infection of the peritoneum." He lays further stress on the fact that the two processes were always separate, even when found in the same gland, one being situated behind the esophagus, where there were two or three very small foci of tuberculosis in addition to the metastastic sarcoma.

Rippert, Claude, and Poncet, on the other hand, were the first to suspect tuberculous toxemia as the cause of many chronic inflammatory and neoplastic processes in the human organism which the microscope had designated as malignant. R. H. Gougerot describes two cases in which the tubercle bacilli had caused inflammations which histologically were identical with spindle-celled and round-celled sarcomata.

The following theses are offered for careful consideration:

1. That circumscribed or uniform enlargement of the thyroid gland is favorably influenced by the injection of tuberculin T.R. manufactured under the supervision of Prof. Ruppel. I have used this tuberculin exclusively, for the reason that one has to be familiar with the peculiarities of the tuberculin employed, and as a surgeon I had no time to try out the various products.

2. That tumors of the mamma, circumscribed and diffuse, which clinically are suspected of being malignant, are also found to react upon injection with tuberculin.

3. No diagnosis of malignancy should stand unless supplemented by the various clinical tests for tuberculosis and syphilis.

Separate articles will be necessary for a detailed description of cases illustrating the first two theses. This paper is confined to the description of two cases of apparently malignant tumors in the abdominal cavity which were cured by tuberculin T.R. injections. Cases similar to my second case have been described by Poncet and Léricheof Lyons and their pupils, but, so far as I know, tuberculin was not employed in any of them as a remedy.

Case I.—Mrs. M. E. D., 56 years old, born in England, youngest of ten children. Mother died at 76 from bronchitis; father at 63 from asthma. Their oldest child died at 61 from cancer; a brother of the patient died at 32 from consumption, a sister at 18 from pneumonia. Patient had pneumonia when eight years old. At 18 she married, had five children, of whom three died in infancy. She had five or six miscarriages from natural causes. While pregnant the first time she contracted erysipelas from her washerwoman.

About ten years ago she had inflammatory rheumatism and soon after developed jaundice. Since that time she has been suffering almost constantly from pains in the right side of her abdomen, severe constipation and hemorrhoidal troubles. Appetite very poor; while food does not cause her distress, she has a distaste for it. Menopause at 45.

Patient was informed by her physician that she had cancer of the womb. Previous to coming to me she had been treated twice a week for a year for womb trouble.

In appearance she looked much older than she was. She was extremely emaciated, no fatty tissue being left. Temperature 100°, pulse 120, heart and lungs normal, considerable increase of physio-

logical cyphosis of the dorsal spine. The adipose tissue of the abdominal walls had so completely disappeared that both hands could easily grasp the liver, which extended down to the umbilicus. There was no other tumor in the abdominal cavity. Uterus and annexa were normal; the slight bloody discharge ceased after a few days. Patient suffered psychic depression (carcinomaphobia) and great prostration; slight icterus.

Diagnosis: Retracted gall-bladder with infection and adhesions to the duodenum or transverse colon, with a possible carcinomatous degeneration of the gall-bladder. Operation at the German Hospital under morphine, scopolamine, and nitrous oxide-oxygen narcosis. The liver was found to be enlarged, of a light yellow color like that in phosphorus poisoning, and studded with innumerable tumors of a gray color, the largest not larger than a pea. Peritoneum normal, smooth, and glossy. Gall-bladder normal, no adhesions. The patient's condition prohibited exploration of the abdominal cavity for primary carcinoma and the abdominal cavity had to be hurriedly closed. Patient recovered from the operation within three days.

A week after the operation 0.0005 of tuberculin T.R. was injected in the arm. A typical local reaction with rise of temperature, nausea, and general prostration followed. This result encouraged me to continue treatment with tuberculin for six months, at intervals of six days to two weeks, with the result that the patient now regards herself as well and able to work. Although the liver has not perceptibly decreased in size, the pains are gone.

Case II.—Mrs. J. R., 42 years old, married at 29; usual diseases of childhood, always healthy except very anemic at puberty. First menstruation at eighteen; menstruation always painful during the first or second day, until after the birth of her first child. Family history as to specific infection and tuberculosis negative, except that one older brother died of consumption. Patient has two healthy boys, no miscarriages.

Ten years prior to present trouble patient had an attack of appendicitis and was treated for the same for five weeks, the treatment consisting mostly of rest and purgatives. After this she had pain in the right side, which would yield to the free use of cathartics. The right side continued to be always very sensitive. At the end of last September, after having attended a series of social functions, the patient was seized with a violent pain in the abdomen, which lasted twenty-four hours. Vomiting was frequent and she could not keep food on her stomach. The patient is well-nourished, with florid complexion. Heart and lungs normal. Stomach meteoristic and tympanitic on percussion. Abdominal walls do not show spastic contraction characteristic of inflammatory conditions.

Diagnosis in suspense. Treatment: No nourishment by mouth. Permanent irrigation of the rectum. Electric light baths over the abdomen. Peristalsis is stimulated by electric light and heat to such an extent that in active inflammatory conditions the pain becomes unbearable by the end of the first fifteen minutes. However, in this case the relief produced by heat and light at the same time proved that there was no acute appendicitis. It took three weeks of the permanent use of cathartics, mostly castor oil and Carlsbad salts, to get rid of the coprostasis. A large amount of white mucus was expelled with the stools. The temperature ranged between 100° and 103°. Pulse at times was weak, 90 to 100. After the colon had been thoroughly emptied there was found in the right iliac fossa a hard tumor, the size of a child's head, which apparently started from the os ilium. The lower border of the tumor was near the horizontal ramus of the os pubis, the upper a hand's breath from the arch of the ribs, and it extended to the middle line. From the umbilicus upwards the tumor felt like a pyramid standing on a broad firm basis. The external border was near the ramus of the iliac bone. The large intestine could not be felt.

From the first my impression was that of a large inoperable osseous sarcoma. The Roentgen picture, however, taken by Dr. Patrick O'Donnell, disproved the connection of the tumor with the os ilium or its periosteum. The rise of temperature, the history, which showed a longer duration than could be the case in malignant growths, suggested the possibility of a tumor of inflammatory origin, although no signs of a tuberculous lesion could be found. Drs. John B. Murphy and Otto L. Schmidt on consultation agreed with this theory.

On October 14 there was given the first injection of tuberculin T.R., 0.0001. This was followed by a typical local reaction and increased pain in the abdomen. From October 14 to November 10 very little nourishment was retained; some days nothing was tolerated by the stomach. October 14, second injection. Temperature before injection 98.6° in the evening; 99.2° on the third day after the injection. November 7, temperature before injection 99°; 100.2° third day after injection. Three days after this injection her pulse became very poor, 128, and digitalis had to be administered during the night. Her psychic condition grew alarming. She could not remember anything and repeated the same questions hundreds of times. There was a decided strabismus divergens which interfered seriously with her vision.

Simultaneously with the appearance of the psychic symptoms there was a marked change in the tumor. It decreased from now on constantly. Taste for food returned; vomiting ceased, and there was a slow but steady improvement in her psychic condition. On November 16 there was observed a parotitis of the right side, which was very painful to the touch and disappeared gradually within a week. There was also an enlargement and sensitiveness of all the lymphatic glands of the neck and inguinal region. November 12, 13, and 14 she was unable to urinate and had to be catheterized. All these alarming symptoms were attributed to the allergic action of tuberculin T.R., so that there was an interval of twenty days before the next injection on November 27. During this time there was a steady though very slow improvement in her mental condition. The minimal dose applied this time produced a rise of temperature of only four degrees. There were further injections with the typical local reaction on December 3 and December 19, when her temperature rose to 99.9° on the 20th. On that date there came with the stools a large amount of glassy mucus and shreds of mucous membrane. On January 11 large tubular pieces of mucous membrane were expelled, preceded by slight colicky pains on the right side. The same occurred on January 3, February 21, and February 24.

Simultaneously the tumor decreased in size and gradually we were able to differentiate the intestine

from the underlying tumor. The wall of the intestine, which felt like a rigid tube, gradually became more pliable and less sensitive to the touch. It could be felt that the part of the tumor which extended over to the rim of the os ilium was in reality an interstitial inflammation of the ileopsoas muscle, for gradually more fibers of the muscle could be felt to emerge from the tumorous mass.

As soon as possible in December the patient was allowed to sit up and enjoy the open air. On January 14 she was able to take her first walk outdoors. During all this time she was given a purin-free and starch-free diet and one to two ounces of castor oil daily. On January 21 examination showed the presence of a great number of typical tubercle bacilli in the feces.

Now, on May 5, the patient is doing well. The tumor has disappeared, only a hard mass just behind the cecum remaining, which appears to be calcified retroperitoneal lymph glands. The cecum and the lower third of the colon ascendens are thickened, but somewhat movable towards the median line. There is no symptom which would indicate a stricture at the valvula Bauhini. Stools are normal. The urine is clear. Appetite good. The patient is able to walk about two miles without fatigue and to climb stairs. Of late her mental condition has been practically normal.

In both these cases the primary tuberculous focus could not be found. In both the clinical diagnosis was malignant growth. In the first case the opening of the abdominal cavity may have benefited the patient, as it is well known that tuberculosis of the peritoneum is favorably influenced by the admission of light and air. In the second case an operation would have been a gross error, as an osteosarcoma of this size and in this location could not be radically removed. The tumor being inflammatory and of tuberculous origin, the establishment of communication with the atmosphere would have given a chance for mixed infection.

Conclusions.—1. Tuberculous toxemia, as well as the tubercle bacillus itself, must be regarded as factors in the etiology of clinically malignant tumors.

2. While both the above cases belong clinically in the province of the surgeon, Case I hardly derived any benefit from the operation, and Case II would have succumbed to an unavoidable mixed infection following laparotomy.

3. The modern surgeon should have at his command the various biological tests, so as to be able to obtain a biological diagnosis before performing any operation for tumors and ulcers.

4. The symptoms of disturbance of the brain in the second case cannot be explained except by assuming an anaphylactic action of the albuminous substances contained in tuberculin T.R.

32 North State Street.

False Hourglass Stomach.—Klose describes cases of so-called spastic or intermittent hourglass stomach which may give the same röntgen picture as the organic affection. It is seen in hysterical vomiting, hysteria without vomiting, in gastric neurosis, and irritable states. A second exposure with negative results may be sufficient for the diagnosis. There is, however, a form of intermittent hourglass stomach due to perigastric adhesions. When empty these stomachs show an hourglass shape which disappears when they are filled. This affection occurs much more infrequently than the purely functional one.—*Deutsche medizinische Wochenschrift.*

SUNSTROKE AND HEAT PROSTRATION.

By ISRAEL BRAM, M.D.,

PHILADELPHIA, PA.

Though sunstroke (insolation) and heat prostration are both due to exposure to excessive heat, the diseases are different in character, each presenting a different symptom complex, and each demanding a different mode of treatment. It is very important to be able to distinguish promptly one disease from the other, for to treat sunstroke as a case of heat prostration or *vice versa* may prove fatal to the patient.

Etiology.—The causes common to both sunstroke and heat prostration are excessive heat and moisture in the air, improper quality or quantity of clothing, unhygienic habits, alcoholism, physical and mental fatigue, overeating, and the presence of a lowered constitutional resistance. One attack of either condition predisposes to another.

Symptomatology.—Sunstroke usually occurs during the afternoon, in persons exposed to the direct rays of the sun, in a still, hot, humid atmosphere. Soldiers on the march, roofers, bricklayers, hucksters, etc., are all liable to insolation or sunstroke. The symptoms of sunstroke are quite characteristic, but may resemble an attack of apoplexy or uremia. There is sudden unconsciousness, with or without convulsions or paralysis, a flushed, hot, dry skin with occasional cyanosis, injected conjunctiva, contracted pupils, high tension bounding, rapid pulse, and irregular respiration, sometimes of the Cheyne-Stokes type.

The temperature must be taken by axilla or rectum, preferably the latter, and is found to be anywhere between 105° and 110° to 113° F. There is suppression of urine, or incontinence of urine and feces. This condition may continue on for from a few hours to a day or more, ending in death through paralysis of the vital centers and asphyxia, or through a complication (pneumonia, meningitis, etc.) or in recovery, with or without such sequellæ as imbecility, poor memory, chronic headache, and an extreme susceptibility to heat.

Heat prostration does not necessarily depend on direct exposure to the sun's rays, but occurs in persons working in close, excessively hot places, as mills, foundries, boiler-rooms, kitchens, etc. The symptoms of heat prostration usually come on insidiously, with such prodromal symptoms of headache, dizziness, nausea, vague bodily pains, and weakness. The patient soon becomes exhausted, and takes to his bed.

The skin is cold, pale, and clammy, there is a rapid feeble pulse, with disordered vision and hearing, and occasionally partial or complete unconsciousness. The temperature is normal, subnormal, or slightly above normal (100° to 102° F.). In grave cases there may be syncope and collapse, though usually an uneventful recovery occurs within a few days.

Diagnosis.—It is of utmost practical importance to differentiate sunstroke from heat-prostration, and from such conditions as apoplexy, uremia, and meningitis. In differentiating, the following points of interest must be remembered: the history of the affection, the mode of onset, the presence or absence of fever, the state of consciousness, the urine, skin, pulse, respiration, and the condition of the reflexes. The following differential diagnosis is useful:

SUNSTROKE (INSOLATION).	HEAT PROSTRATION.
1. History of direct exposure to the sun.	1. History of exposure to excessive heat, usually indoors.
2. Onset sudden, often with convulsions or paralysis.	2. Onset gradual, no convulsions or paralysis, but prodromes (headache, dizziness, nausea, etc.).
3. Complete unconsciousness.	3. Rarely loss of consciousness.
4. Skin hot, flushed and dry.	4. Skin cold, pale, and clammy.
5. Injected conjunctiva, contracted pupils.	5. Conjunctiva pale, pupils dilated, or normal.
6. Temperature very high (105° to 113° F.).	6. Temperature normal, subnormal, or slight fever (100° to 102° F.).
7. Pulse high and bounding.	7. Pulse weak and thready.
8. Respiration irregular, often Cheyne-Stokes in type.	8. Respiration shallow and sighing.
9. Course brief, with guarded prognosis, terminating in death or recovery in from a few hours to a day or more.	9. Course greater in duration, and prognosis good, usually terminating in recovery within a few days.

Treatment.—The treatment may be considered under the heading of (*a*) prophylactic, and (*b*) treatment of the attack.

The prophylactic treatment of sunstroke and heat-prostration consists in overcoming the causal factors. Overeating and indulgence in alcoholic beverages should be avoided. Proper ventilation at home and at work, frequent cold sponges or baths, and the wearing of light-colored, light-weight clothing are imperative. The function of the bowels, skin, and kidneys must be kept in a normal state. Physical and mental fatigue and prolonged exposure to the sun's rays should be avoided. The imbibition of copious quantities of wholesome water (not ice-water) is particularly beneficial, by promoting the action of the skin and kidneys.

The treatment of the attack in sunstroke is decidedly different from that of heat prostration. In the former, excitation is a decided symptomatic feature, in the latter, depression.

The subject of a *sunstroke* should be immediately immersed in an ice-water bath, kept at a temperature of 40° F., during which time the skin should be rubbed vigorously to bring the heated blood of the interior to the surface of the body. The lowering of the body temperature should not be too sudden, else fatal collapse will result. If the fever has been reduced to 102° or 101° F. the patient should be removed to a cot in the shade and covered with a sheet. The rectal temperature should be frequently taken, and any marked rise should be combated with more ice baths. In marked cases venesection, with the intravenous injection of physiological saline solution, will result happily. The head should be kept cool by means of an ice cap, and the feet may be bathed in hot mustard water. In the event of cardiac weakness, hypodermic injections of strychnine or camphor and ether should be given. In some cases ice water enemata or the needle spray of cold water may be given. A course of calomel should be given to clean the bowels and overcome hepatic torpidity. As soon as food can be taken, liquid diet should be given, including skimmed milk, buttermilk, orange-albumin, and plenty of water.

It must be remembered that one attack of sunstroke predisposes to another, so that due precautions must be taken to avoid them. It may be necessary for some patients to remove to a cooler climate.

A patient with *heat prostration* should be treated, in some respects, entirely different from one with sunstroke. Here we often have subnormal temperature, necessitating a *hot* bath. If the temperature is above normal, sponging with moderately cold water will soon overcome it, but an ice bath *must not be given*. Keep the patient in a cool place, avoid constricting clothing about the neck and chest. To overcome the tendency to syncope, aromatic spirit of ammonia, spirit of glonoin, or inhalations of amyl nitrite may be given. Strychnine, digitalis, iron, and a concentrated nourishing diet should be given to combat weakness in convalescence. When recovery is complete, measures to avoid a relapse should be instituted.

In conclusion, it would be wise to say that observance of common-sense dietetic and hygienic rules, proper clothing, the avoidance of alcoholic beverages and other conditions which tend to devitalize the system will serve to prevent both sunstroke and heat prostration.

1714 N. Seventh Street.

Hyperostosis Cranii.—E. B. Waggett and E. D. Davis report the case of a newsman, aged 22, who complained of swellings of the face and of nasal obstruction. He first noticed the swellings at about the age of 16, one month after receiving "a punch on the nose." He had never been abroad, and none of his family were similarly affected. He was given a mixture of mercury and potassium iodide for six weeks, and no change in his condition was noted. The patient was of poor physique, but well nourished, and had well-marked symmetrical osseous swellings involving the nasal processes of the maxillæ and extending on to the facial surfaces of the bodies of the maxillæ. The maxillary antra were opaque to transillumination, but the frontal sinuses were normal. The nasal bones were unaffected, but both sides of the nose were obstructed by the hard osseous swellings, which could both be felt and seen within the nostrils. The infraorbital margins were involved and there was lacrymal obstruction on the right side, but in other respects the orbits were apparently normal. The optic disks were normal. In addition, there was a diffuse smooth swelling of the body of the mandible, to the right of the mental eminence, and surrounding the mental foramen. The teeth were carious and there was considerable oral sepsis. The left ear was normal, but he had otitis media on the right. There were neither signs nor history of syphilis, but the Wassermann reaction was positive. Skiagrams showed both maxillæ occupied by dense masses of bone. The rest of the skeleton was normal.—*Proceedings of the Royal Society of Medicine.*

Fractures and Separations of the Epiphysis in Children.—Savariaud has found evidences of the consolidation of intrauterine fractures in new-born children. Fractures are much more frequent than dislocations in children. They consolidate very quickly, and in the frequent greenstick fractures the child may use the limb for some time after the partial fracture has taken place, and the diagnosis may be made only when the exuberant callus is present. Rachitis and prolonged immobilization of the limbs in plaster act as predisposing causes of fracture, since there is absorption of bone in them. Separation of the diaphysis and epiphysis occurred frequently since there is a zone of imperfect ossification at the point of least resistance. A violent distortion of the ligaments occurs, and the periosteum remains attached to the epiphysis that is being separated from the diaphysis. If complete reduction does not occur there will be formed a band of constriction due to rapid ossification at this point which will cause an arrest of development of the bone.—*Journal de Médecine de Paris.*

MEDICAL RECORD.

New York, July 27, 1912.

RECENT PROGRESS IN THE STUDY OF PNEUMONIA.

At no time more than the present has the prospect seemed brighter that a successful serum-therapy of pneumonia would be achieved. Many years of patient clinical and epidemiological study have contributed naught of any real value in reducing the high mortality or curbing the increasing prevalence of this disease. The ubiquity of the pneumococcus, and the danger of the healthy individual becoming the innocent carrier of even malignant types of this microorganism, were clearly revealed by the investigations carried out nearly a decade ago by the Pneumonia Commission of the City of New York. Pneumonia is a disease that presents many difficult bacteriological and clinical problems. These have been surveyed in a most illuminating manner in the Lumleian lectures recently delivered by Percy Kidd before the Royal College of Physicians of London, and abstracted in recent issues of the MEDICAL RECORD. One of the important facts emphasized by Kidd is that the frequency with which pneumonia appears under the guise of a general infection without local manifestations stamps this disease as of septicemic origin. The researches of Neufeld and Haendel have shown that the crisis in pneumonia depends on the formation of antibodies, which can be recognized experimentally in animals and in the blood of convalescents from pneumonia. These observers have pointed out that the therapeutic value of the antibodies depends upon the production of a sufficiently potent serum, and on the rapid introduction of large quantities of the latter into the human body. In this connection there must not be overlooked the recent discovery by Lamar that the coincident injection of sodium oleate greatly increases the efficacy of this serum.

Two important papers in which are set forth the results of his studies on pneumococcus infection in animals are presented by Augustus B. Wadsworth in the *Journal of Experimental Medicine,* July 1, 1912. The first of these papers deals with the action of pneumococcus cultures on animal tissues, and the action of immune sera on the pneumococcus. The fact is emphasized that lobar pneumonia is only one phase of pneumococcus infection. The injection of culture filtrates of the most virulent pneumococci causes little or no disturbance, nevertheless the animal at the same time develops an immunity to the action of virulent living pneumococci. The same is true if dense suspensions of pneumococcus cells are used instead of the filtrates. From these experiments it is concluded that dead cultures of the pneumococcus do not contain the active poisons elaborated by the organism in infection, and that these cultures contain altered or degenerated poison which, when liberated in infection, gives rise to more powerful poisons, but when formed in culture is active only as antigen. As the result of further experiments it was shown that virulent pneumococci are extremely insusceptible to phagocytosis owing to the presence of substances retained by the pneumococcus cell even after it is killed by heat. As long as these substances are retained by the pneumococcus they are not acted upon by an immune serum; but when liberated they are rendered inert by the latter. Nonvirulent strains of pneumococci are subject to phagocytosis. The insusceptibility of virulent pneumococci to the latter action is attributed chiefly to qualities acquired by the microorganisms during their propagation through animals. Under certain conditions in the tissues the virulent cells are so altered that they become susceptible like the nonvirulent strains. In man and the dog phagocytosis is active during recovery, but in the rabbit this action does not appear.

In the second paper Wadsworth discusses the action of immune sera on pneumococcus infection. He suggests that in lobar pneumonia of man the lung lesion plays a minor part in determining the disease as a whole, the bacteriemia being responsible for many of the manifestations seen at the bedside. The protective mechanism of the lung is, however, far more efficient than that of the blood stream, for material that is infectious when inoculated under the skin or into a vein in the dog or rabbit, is innocuous when injected into the lungs through the trachea. The extensive lesion in the lung in lobar pneumonia is an expression of the individual's protective mechanism, which may be adequate or inadequate. In man and in the dog extensive lung involvement may cause little discomfort, and serious symptoms may develop even when the lesion in the lungs is comparatively slight. Symptomatically the disease is a systemic reaction to the poison, whether this is derived from the lung lesion or from the bacteriemia. These facts are strikingly illustrated in the case of experimental pneumonia in the rabbit and dog. In the former pneumococci develop without local tissue reaction; the protective mechanism is slight and inadequate, and the animals quickly die from the bacteriemia. On the other hand, the dog is relatively insusceptible, the pneumococci causing an extensive local tissue reaction, and although extensive lung lesions are present there is neither sustained temperature nor recovery by crisis as in man.

Taking his cue from the facts that in man or animals recovery is due to the immunity incited and that previous attempts at achieving a serum-therapy were focused on one phase of immunity as a whole, Wadsworth has succeeded in preparing sera in animals by means of injections with virulent pneumococci, which sera are effective in curing pneumococcus infection in the most susceptible

animals. The details of Wadsworth's experiments may be obtained by consulting the original paper. It will suffice to present in this review his main conclusions. He notes that immune sera vary greatly in their curative value, and that while certain sera may possess protective value, this is not necessarily indicative of curative action. Treatment with the serum of normal rabbits may prolong the course of pneumococcus infection in the rabbit, but this action is slight. Sera from animals immunized with dead pneumococcus cells washed free from their products, and sera from animals immunized with culture filtrates free from pneumococcus cells, possessed only a slight curative value. On the other hand, when an animal was immunized with virulent living cultures its blood serum acquired a marked curative action. After pneumococcus infection in the rabbit had become established, treatment with this serum induced crisis and cured the animal. Virulent pneumococci are singularly insusceptible to the action of immune sera in the test tube, nevertheless they succumb to these sera in the body of the infected individual.

"Diphtheria and tetanus organisms," states Wadsworth, "give rise to powerful toxins, but the parasitism of these organisms is slight and their development is localized. Diseases produced by these organisms are toxemias and neutralization of their toxins by antitoxin puts an end to the disease. The pneumococcus gives rise to toxic substances which are less active or active only in the body tissues, but the parasitism of this organism is marked and its development is rarely localized. Nevertheless, the manifestations of the disease arise from the action of the bacteria poisons on the tissues. The neutralization of the pneumococcus poisons by immune serum puts an end to the symptoms of the disease, but the pneumococci survive as harmless parasites until destroyed by lysis or phagocytosis." It is pointed out that crisis is simply one phase of recovery which does not differ fundamentally, whether it is sudden and complete, as in crisis, or incomplete or prolonged, as in lysis. Both processes represent the neutralization of the pneumococcus poison. The pneumococci themselves are destroyed by lysis extracellularly in the rabbit and intracellularly by the process of phagocytosis in the dog and in man.

It is to be hoped that in the near future there will be available for the treatment of lobar pneumonia in man the immune sera which Wadsworth has found so effective in curing the disease in the rabbit, which is most susceptible to the toxic action of the pneumococcus. In attaining results that will no doubt contribute to the saving of many valuable lives the fruits of patient investigation conducted with one definite object in view will be amply realized.

PRESENT STATUS OF THE EPIDEMIOLOGY OF BUBONIC PLAGUE.

Although presumably trustworthy accounts of bubonic plague are readily accessible, the great fluctuations in individual epidemics render valuable all special information based on observation of current episodes; and it is also highly instructive to contrast contemporary epidemics in different parts of the world. For example, some accounts of the pneumonic form state that there are no survivors, which fact is only reassuring in as far as it excludes the possibility of carriers. But we learn that in Egypt the mortality from this form was but 85 per cent. and that the survivors became dangerous carriers, bearing the germs in their respiratory organs for a long time and menacing their environment by coughing and expectorating.

At a recent session of the Aerztlicher Verein of Munich (*Berliner klinische Wochenschrift,* July 1) Dieudonné summed up our contemporaneous information on the epidemiology of the disease, and stated among other facts that it progresses but slowly from house to house. For this reason we do not see pandemics nowadays, and in communities with a very mixed population socially, the higher classes may escape throughout as a result of their superior knowledge and sanitary prophylaxis. This, of course, holds good for typhus, cholera, and variola, but is in marked contrast with other epidemics like influenza, measles, etc., which alone are truly pandemic.

The chief increase in our knowledge of epidemiology is connected with animals—domestic and wild. It is now known that the rat suffers from the disease in a peculiar chronic form, located principally in the spleen. This disease has an exacerbation in the warm months.

If the disease were not insect borne its incidence, both in man and animals, would modify the epidemiology profoundly. Perhaps there is no affection in which so many different species of insects act as intermediaries. The author enumerates bedbugs, ants, fleas, and mosquitos (the latter possibly a misprint—culex for pulex?). The rodents in a community, therefore, become quickly infected. For many years when this plague lay fallow in the tropics cases were reported now and then from Asiatic Russia. We can now realize that the petty episodes described during these years must have been due to some of the wild rodents. Had rats been affected the disease should have been much more prevalent. It is now known that the feces of the flea can transmit the disease.

The prophylaxis of the disease at the present day includes quarantine disinfection with certain gases, destruction of rats witth phosphorus, personal cleanliness, masks and suits for doctors and nurses, and inoculation with dead cultures of the *Bacillus pestis.*

THE SIGNIFICANCE OF GASTRIC STAGNATION.

So much has been written and taught about the value of the chemical examination of the gastric contents after a test meal that the examination of the fasting stomach has been lately much neglected. Yet no examination of the gastric functions is complete without the determination of the presence or absence of stagnation of food, and such determination is frequently much more valuable as a therapeutic indication than one or another deviation from the normal chemical character of gastric juice. Moreover, gastric stagnation is by many thought to

be present only when large quantities of food remains are obtained in the morning before breakfast; that this, however, is not the case is the earnest plea of Dr. E. Fricker in a recent number of the *Correspondenz-Blatt für Schweizer Arzte* (Vol. XLII, No. 12). This writer's numerous examinations have shown that normally in the morning the stomach is either quite empty or contains a little mucus, swallowed saliva, or gastric juice, but no food remains. This results in a sort of "self cleansing" of the stomach, so that the numerous bacteria, etc., introduced with the food are deprived of sustenance and are not unduly numerous in the normal stomach. Quite different, however, is the state of affairs when stagnation of food is present, though it be of microscopical nature only, the material for its determination being obtained from the particles adherent to the fenestrations of the stomach tube or by centrifuging the stomach contents obtained through the tube. Here bacteria are abundant and the most significant of these are sarcinæ and the well known Boas-Oppler bacilli. The former may be present even if hyperacidity exists, and, according to Fricker, their presence is an indication of stagnation even though at certain times they are not accompanied by food remains. Boas-Oppler bacilli, on the other hand, are quickly destroyed by high acid content; moreover, they are significant only when present in numbers sufficiently large to make them very conspicuous throughout the field of vision of the microscope.

How close is the relation between stagnation of the stomach contents, the presence of sarcinæ and Boas-Oppler bacilli, and the functional disturbances of the stomach, is well shown by a series of cases observed by Fricker. In 27 cases of stagnation with little change in the chemical character of gastric juice, in 25 of which benign stenosis of the pyloris was shown at the operation, sarcinæ were constantly present in the material obtained from the fasting stomach. On the other hand, out of 23 cases of gastric cancer with marked deviation from the normal chemical character of the gastric juice, Boas-Oppler bacilli were found in abundance in 21 cases.

Accordingly, Fricker recommends the following procedure in examining a patient with gastric symptoms: (1) An evening meal consisting of soup or milk, meat, and rice. (2) Emptying the stomach next morning, about twelve hours later, and careful examination of the food remains if obtained, or of the particles adherent to the tube. If nothing is obtained, lavage and examination of the sediment of the wash water. (3) Test breakfast, and examination of the chemical character of the gastric contents obtained after it. Of course, the microscope must be employed for the discovery of sarcinæ, Boas-Oppler bacilli, and the study of the minute particles of food, their behavior on addition of Lugol's iodine solution, etc., etc.

The therapy of gastric stagnation advocated by Fricker is radical. He grants that medical measures, such as dieting, lavage of the stomach, etc., may keep the symptoms in abeyance. However, competent surgery, in most cases the operation of gastroenterostomy, is preferred by Fricker as a really curative therapy.

Intubation of the Aorta.

The feasibility, at any rate in the dog, of an operation that may eventually prove of service in the treatment of aortic aneurysm and of traumatic lesions of the aorta in human beings, has been demonstrated by A. Carrel (*Journal of Experimental Medicine*, July 1, 1912). This investigator has already shown that a segment of vein can be successfully grafted on the thoracic aorta; that wounds of the abdominal aorta can be repaired by means of a piece of rubber covered with vaseline, and that the circulation can take place for six days through a paraffined glass tube lying free in the abdominal aorta. These experiments were all performed on dogs. In the latest developments of his investigations along this line, Carrel inserted into longitudinal incisions in the thoracic aorta of dogs paraffined tubes of glass or aluminum, nine or ten millimeters in diameter and forty-five millimeters long. The tubes either distended the vessels, fitted them exactly, or were smaller than the caliber of the aorta. The tubes were fixed in this artery by means of silk ligatures that had been put around the vessel previously. The results of the experiments thus far performed have shown that aortic blood can flow through a glass tube for more than three months without the occurrence of an obliterative thrombus. Laceration of the arterial wall causes a deposition of fibrin and partial or complete occlusion of the tube or vessel. Carrel suggests that the use of a tube of proper caliber, form, and composition, as a smooth-edged gold tube of relatively small caliber, may be followed by better results; and that it is possible to line the tube with a vein in order to prevent more surely the occurrence of a thrombus.

Pseudotuberculous Experimental Leprosy.

The analogy between the bacilli of Koch and of Hansen has been noted from the very outset of bacteriology. So marked is it that much wonder has been expressed as to the very dissimilar character of the two diseases caused thereby. That two such processes should be so infectious and malignant, caused by such similar organisms, and yet differ so much among themselves, and present so few points in common constitutes a paradox, especially when we bear in mind the close resemblances between syphilis and yaws, two affections which also show a marked analogy in their causative agencies. Recent experiments appear to show that in experimental medicine this dissimilarity will not obtain and that the lesions of experimental leprosy will be found to bear a very close resemblance to both clinical and experimental tuberculosis. It has long been know that lepers react positively to tuberculin and recently it has been learned that tuberculous subjects give positive reactions to nastin. At a meeting last winter of the Aerztlicher Verein of Hamburg (*Berliner klinische Wochenschrift*, June 10) Much reported that animals previously sensitized with sterile cultures of tubercle bacilli became susceptible to leprous inoculation. In guinea pigs and goats alike subcutaneous injections of leprosy bacilli set up what appeared to be typical tuberculous cold abscesses, the size of a bean to that of a pigeon's egg. The pus was creamy and poor in cells and contained bacilli in abundance. To what extent the tuberculous type of lesion could have been due to the sensitization is naturally not in evidence.

News of the Week.

The Plague Situation.—Up to July 19 no new cases of plague had developed for several days in either Cuba or Porto Rico, yet as examinations of a large number of rats in Porto Rico had shown the presence of the infection in at least 2.5 per cent. of the animals, the Government officials were increasing rather than relaxing their watchfulness. Wisely, as it appeared, for on July 20 three new cases were discovered in the suburbs of San Juan, making a total of thirty-seven cases and twenty-six deaths in the island since the disease was first recognized. The commission, consisting of Col. Jefferson R. Kean, Major Frederick F. Russell, Lieutenant Fred H. Foucar, and F. Y. Howard, sent from Washington to study conditions as regards the plague in Porto Rico, reached New York on July 15. In Havana a third case was discovered on July 23. Unofficially it was stated that while the disease had been checked for the present in San Juan, the commission considered that it would be impossible to eradicate it until modern sanitary methods had been introduced and especially until all the dwelling houses had been raised from the ground. The sanitary conditions in the surrounding country were found to be very bad. In all the larger ports of the United States the health authorities are paying careful attention to the situation and watching all incoming ships and passengers. The Health Officer of the Port of New York has announced that as the result of some experiments it has been decided that anhydrate liquefied sulphuric acid gas will prove to be efficient as a destroyer of rats on ships as well as being quicker and more easily handled than the old method, and that he will therefore adopt its use here. The Health Officer has also been empowered by Governor Dix to expend whatever money is necessary to fumigate all ships entering the harbor from infected ports, using the fees collected by his office. In Philadelphia, the Director of the Department of Health and Charities, wishing to make a personal examination of all rats in the city for the purpose of ascertaining if any were infected with bubonic plague, issued a call to the citizens on July 15 to take all rats possible to his rooms in the City Hall. The response was so immediate and hearty, however, that three days later he was compelled to withdraw his invitation, having come to the conclusion that Philadelphia was largely populated by these animals.

Poliomyelitis.—A number of cases of infantile paralysis have appeared in this city, probably the forerunner of an epidemic of the disease as predicted in the MEDICAL RECORD of last week. In Buffalo, N. Y., eight cases were discovered by inspectors of the Department of Health on July 20. None of the cases had been reported, and the Health Commissioner ordered the attending physicians to appear before him on July 22 and show cause why they should not be prosecuted. Dr. Neustaedter writes that an investigation is being conducted at Cornell Medical College regarding the infectivity of dust, and requests that information be sent to the college regarding cases, or suspected cases, in order that the sweepings of the sick-room may be collected and examined.

Lectures on Hygiene.—The New York State Department of Health has undertaken the education of women and girls throughout the State in the subject of sex hygiene. The work will be carried on in connection with existing institutions and organizations as far as possible, and by means of lectures, circulars, and exhibits. The following staff of special lecturers has been appointed: Dr. Rosalie S. Morton, New York; Dr. E. Hamilton Muncie, Brooklyn; Dr. Lusia E. Heaton, Canton; Dr. O. M. Grover, Dunkirk; Dr. Mary H. Potts, Elmira; Dr. Adelaide Dutcher, Syracuse; Dr. Agnes E. Page, Albany; Dr. Cora B. Lattin, Buffalo; Dr. M. May Allen, Rochester; Dr. Ina V. Burt, Phelps; Dr. Mary G. Day, Kingston; and Dr. Angeline Martin, Utica. The New York State Cancer Laboratory will cooperate in preparing lectures dwelling upon the early diagnosis, means of prevention, and necessity for early skilled treatment of cancer.

Danger of Rabies.—The Board of Health of New York City at a recent meeting adopted a special order calling for the shooting of unmuzzled dogs in the Borough of Richmond where, for some time past, complaints of dogs running at large have been unusually frequent and where a number of persons have been bitten. Since January 1, 1912, among 210 dogs sent to the Department of Health from the Borough of Richmond for examination, seventy cases of rabies were found. The ordinary jurisdiction of the Department in the matter of dog bites extends only to the removal of such dogs for observation and their destruction if found rabid or vicious to such an extent as to render them unfit to be at large. At times of special danger fram rabies, however, the Board of Health under its general power to abate nuisances to protect the public health may adopt a special order calling for the killing of unmuzzled dogs on the streets, as it has done now. Commissioner Lederle also suggests that it may be necessary to extend the special order to include other boroughs unless the general ordinance requiring the muzzling of dogs is more generally complied with.

A Cure for Diabetes Not Found at Cornell.—Dr. W. M. Polk, Dean and Director of the Cornell University Medical College, writes: "A recent publication in the public press to the effect that a 'cure' for diabetes had been found and that it had been worked out under the auspices of the Cornell University Medical College has been called to my attention. Please state that our School knows nothing of the 'cure' or of the measures pursued to establish its value."

Car Hits Ambulance.—An ambulance from St. Vincent's Hospital, New York, answering a sick call, was struck by a Seventh avenue car at Elizabeth and Grand streets on July 17, and overturned. Dr. Kilbourne, the surgeon in charge, was bruised and shaken up, and the driver of the ambulance sustained a fractured collar bone.

Canal Zone Report.—The Department of Sanitation of the Isthmian Canal Commission, through Dr. John L. Phillips, Acting Chief Sanitary Officer, reports that during the month of May, 1912, there were among the employees a total of 33 deaths, of which 19 were due to disease and 14 to violence, making a total annual average death rate per thousand of 8.01, which is only slightly larger than the very low rate recorded for May, 1910. Five deaths were due to Bright's disease, 5 to lobar pneumonia, and 3 to pulmonary tuberculosis. The report closes with the words which have become so usual as almost to be overlooked: "No cases of yellow fever, smallpox, or plague originated on or were brought to the isthmus during the month."

Campaign Against Hookworm.—The Texas State Board of Health has begun a campaign for the eradication of the hookworm in that State, under the direction of Dr. M. H. Boerner of Washington, D. C. It has been found that the infection is particularly heavy in East Texas, 50 per cent. of the total population in some counties being infected.

Sues Telephone Company.—Dr. John Allen Hawkins of Pittsburg, Pa., has brought suit against the Bell Telephone Company, claiming damages to the amount of $25,000 because of the omission of his name from the Pittsburgh telephone directory.

Bad Eggs Kerosened.—Dr. R. B. Fitz-Randolph of the pure food division of the New Jersey State Board of Health on July 17 seized 1,000 pounds of eggs in the warehouse of a refrigerating company in Jersey City, and the eggs being unfit for use were treated with kerosene in order to prevent their sale.

Dr. Simon Baruch has been appointed consulting hydrotherapist to Bellevue, Gouverneur, Harlem, and Fordham Hospitals.

Dr. Herbert J. Smith of Philadelphia has been elected professor of dermatology in the Medico-Chirurgical College of that city, and will also act as professor of materia medica and anesthetics in the dental department of the college.

City Death Rate.—For the week ending July 13, the general death rate per thousand in New York City was 14.02, as against 18.22 for the corresponding week of last year, the difference of 4.20 points being equivalent to a decrease of 416 deaths. Although the temperature during the week was very high, the number of deaths from sunstroke was only 42, while in the same week of 1911, 288 deaths were ascribed to this cause. There was also a decrease of 50 in the number of deaths of infants under one year of age. For the first twenty-eight weeks of 1912 the death rate was 14.90 as compared with 16.35 for the same period of 1912.

New Hospital Dormitory.—The Willard Parker Hospital, New York, is to be enlarged by the erection of a five-story dormitory for which plans were filed recently with the Building Department. The new building will have a frontage of 51 feet on Fifteenth street and a depth of 100 feet, will be constructed of reinforced concrete, and will be fireproof. The cost is estimated at $80,000.

Two "Scientists" Die.—Within ten days of the death from scarlet fever of his thirteen-year-old daughter, Clayton J. Whipple, a Christian Scientist of Yonkers, N. Y., died of the same disease, having refused to permit medical treatment of either his daughter or himself. Both patients were attended by Christian Science practitioners who, in spite of their non-belief in disease, notified the Health Department of the existence of a contagious disease, and made no attempt to interfere with the establishment of a quarantine of the house and family.

Favor Marriage Restrictions.—The members of the New Jersey Branch of the Lutheran Synodical conference in session at Closter, N. J., recently went on record as opposing the issuance of marriage licenses unless the applicants were able to produce a physician's certificate to the effect that both are physically fit to marry.

Official Dipterologist.—The Director of the Department of Public Works of Philadelphia recently appointed an official mosquito slayer to that city at a salary of $3.85 a day, the city having made an appropriation $5,000 for the conduct of a war on these pestiferous insects. The title of "dipterologist" has been conferred upon the appointee whose reputation as a destroyer of mosquitos is said to be unequaled.

Investigating Milk Supplies.—At the request of the Trenton, N. J., City Commission, the Chief of the Division of Creameries and Dairies of the New Jersey State Board of Health is conducting an investigation into the 400 sources of the milk supply of the city, with a view to stopping the sale of unwholesome milk and punishing the offenders. Trenton at present has no system of milk inspection of its own.

Open Grenfell Institute.—Interesting ceremonies marked the opening on July 15 of the King George V. Institute for Fishermen and Seamen, at St. John's, Newfoundland, erected under the direction of Sir Wilfred Grenfell, medical missionary to Labrador.

Gift for Hospital Home.—The French Benevolent Society announces a gift from four of its friends of $40,000 for the completion of a $125,000 fund to be used to build a home for the aged and a training school for nurses in the rear of the French Hospital on West Thirty-fourth street, New York.

American Association of Clinical Research.—The fourth annual meeting of this society will be held in the New York Academy of Medicine, New York City, on November 9, 1912. There will be morning, afternoon, and evening sessions, the general public being invited to attend the last, and a notable program is in preparation. This association recognizing "the necessity for clinical research that shall produce a body of unquestionable clinical facts from which therapeutic principles may be deduced," aims to form centers of clinical research in all of the larger cities, such centers to endeavor to interest physicians, hospitals, and the public. Dr. James Krauss, 419 Boylston street, Boston, is the permanent secretary. Physicians in general are invited to attend the meeting.

Physicians' Association. — The New York Physicians' Association of the City of New York was incorporated in the Supreme Court on July 15. The purpose of the society is the holding of clinical meetings and scientific sessions, and it numbers among its incorporators Drs. Herman C. Freudenthal, William S. Gottheil, A. E. Isaacs, Robert Abrahams, and H. G. Watson.

Kentucky Health Officers.—The State and County health officers of Kentucky held their first annual conference in Louisville recently, every county officer being obliged to attend. The expenses of the conference were provided for in the annual appropriation given to the State Board of Health.

Typhoid Carrier.—The occurrence of a dozen cases of typhoid fever among children living in the same neighborhood in Elgin, Ill., recently, has caused the health authorities, after negative investigations of the water and milk supplies, to suspect that the disease is being spread by a typhoid carrier, similar to the famous "Typhoid Mary" of New York.

A Successor to Dr. Wiley as chief of the Bureau of Chemistry in the Department of Agriculture will shortly be appointed. The successful candidate is said to be Dr. James H. Beall of Scioto, Ohio.

Delegates to the British Medical Association.—Dr. Arthur W. Yale of Philadelphia and Dr. W. Benham Snow of New York sailed on July 11 for England, where they are attending the meeting of the British Medical Association in Liverpool.

Dr. W. W. Richardson, for six years physician-in-chief to the men's department of the Eastern Pennsylvania Hospital for the Insane at Norristown, has resigned as of October 1st, to engage in private practice.

The Fourth in New York.—A good indication of the wiser observance of the Fourth of July in New York is contained in the announcement of the Board of Ambulance Service that there were on that day this year 277 calls, or only 16 more than the daily average in all boroughs throughout the year, and 67 less than on the Fourth of July, 1911. The greatest decrease occurred in the Borough of Manhattan where the number of calls fell from 196 to 130. It is a matter of some congratulation that this year at least our national birthday was not celebrated by wholesale death and injury. In one thing, if not perhaps in all, we are becoming saner.

New Pasteur Institute.—The foreigners resident in Bangkok, Siam, are endeavoring to establish a Pasteur Institute there, not only for the treatment of rabies, but for bacteriological and serological work, and a meeting was held recently at the Hongkong and Shanghai Bank for the purpose of raising funds for the project.

American Hospital Association.—The fourteenth annual meeting of this association will be held in the Hotel Pontchartrain, Detroit, Mich., on September 24 to 27, 1912, under the presidency of Dr. Henry M. Hurd of the Johns Hopkins Hospital, Baltimore. Details as to the programme, etc., may be obtained from the secretary, J. N. E. Brown, M.B., 90 Charles street, East.

Pan-American Congress.—The Sixth Pan-American Congress will meet in Lima, Peru, on August 3 to 10, 1913, in connection with the Latin American Medical Congress and the Congress of Hygiene. The congress will be under the patronage of His Excellency the President of Peru and of the Minister of Foreign Relations, of Instruction, and of Fomentation. Its work will be divided into eight sections, covering anatomy and physiology; bacteriology and parasitology; medicine, surgery, hygiene, physics, chemistry, natural history, pharmacology, veterinary medicine, and odontology. Various excursions through the country are being arranged for those attending the congress, as well as many different means of making the journey to and from Peru.

Second District (South Carolina) Medical Association.—The annual meeting of this society was held at Blackville on July 2, and officers for the ensuing year were elected as follows: *President,* Dr. Josiah S. Matthews, Denmark; *Secretary-Treasurer,* Dr. Sophia B. Brunson, St. Matthews.

Dubuque County (Iowa) Medical Society.—At the annual meeting held in Dubuque on June 26, the following officers were elected: *President,* Dr. William L. Becker, Dubuque; *Secretary,* Dr. Mathias J. Moes, Dubuque; *Treasurer,* Dr. Anthony M. Loes, Dubuque.

Physicians' League.—Under this title a number of physicians of Brooklyn, N. Y., organized, on July 5, a new society for the study of economical and social phases of medicine.

Obituary Notes.—Dr. John Joseph Lawlor of Lawrence, Mass., a graduate of the Baltimore Medical College in 1897, and a member of the Galen Medical Society and the Amalgamated Physicians' Protective Association, died at his home on July 8.

Dr. Miles J. O'Reilly of Fishkill-on-the-Hudson, N. Y., a graduate of the Albany Medical College in 1874, died in St. Luke's Hospital, Newburg, on July 11, aged 60 years.

Dr. George S. Gove of Whitefield, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1858, and a member of the New Hampshire State and Coos County Medical Societies, died at the home of his daughter in Greensboro, N. C., on June 28, aged 83 years.

Dr. James A. Miller of Sante Fe, New Mexico, a graduate of the Cincinnati College of Medicine and Surgery in 1870, formerly a member of the Pennsylvania State Board of Medical Examiners, and a member of the New Mexico State and Santa Fe County Medical Societies, died suddenly of heart failure on June 29, aged 68 years.

Dr. John Boyce Donaldson of Canonsburg, Pa., a graduate of the Medical Department of Western Reserve University, Cleveland, Ohio, in 1872, a member of the American Medical Association, of the Medical Society of the State of Pennsylvania, of which he was a former president, and of the Washington County Medical Society, having served the latter as secretary for many years, died at his home on June 29, aged 64 years.

Dr. John Russell Goodloe of Demopolis, Ala., a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., in 1893, and a member of the Alabama State and Marengo County Medical Societies, died at his home of nephritis, on July 1, aged 43 years.

Dr. Nathan Mayer of Hartford, Conn., a graduate of the Cincinnati College of Medicine and Surgery in 1859, a member of the American Medical Association and of the Connecticut State and Hartford County Medical Societies, a veteran of the Civil War, having served as surgeon with the Sixteenth Connecticut Volunteers, and well known as an author and dramatic critic, died in the Hartford Hospital, on July 10, aged 73 years.

Dr. William H. Weirick of Washington, Ill., a graduate of the Jefferson Medical College, Philadelphia, in 1866, a member of the American Medical Association and of the Illinois State and Tazwell County Medical Societies, and a veteran of the Civil War, died at his home, on June 28, aged 70 years.

Dr. Henry Edwin Spalding of Boston, Mass., a graduate of the New York Homeopathic Medical College and Hospital in 1866, for many years visiting physician to the Homeopathic Hospital of Boston, and later consulting physician, and formerly president of the Massachusetts Homeopathic Medical Society and of the Massachusetts Surgical and Gynecological Society, died at his home in Hingham, on July 4, aged 68 years.

Dr. Thomas H. Bache died at Philadelphia on July 8 at the age of 86 years. He was graduated from the University of Pennsylvania in 1846 and from Jefferson Medical College in the class of 1850. He was a resident physician in the University Hospital in 1852 and 1853. He was one of the founders of the Children's Hospital and at one time surgeon to this hospital and also to Howard Hospital. During the Civil War he was surgeon to the 17th Regiment of Pennsylvania Volunteers, major and brevet lieutenant-colonel medical corps U. S. A. from 1861 to 1865. He was in charge of the United States Army Hospital at Chester, Pa. He was a Fellow of the College of Physicians of Philadelphia, a member of the American Philosophical Society. He was a great-great-grandson of Benjamin Franklin.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

LONDON HOSPITAL—UNIVERSITIES CONGRESS—RETRACTION RINGS AS OBSTACLES TO DELIVERY—ROYAL COLLEGE SURGEONS MUSEUM—INSURANCE—BRISTOL INFIRMARY—THE KING'S VISIT—OBITUARY.

London, July 5, 1912.

On Monday Lord Roseberry distributed the prizes at the London Hospital College and gave one of those charming addresses for which he is noted. He began with some amusing talk about students in the past referring to horrible pictures which humorists conjured up as mere antediluvian animals for peripatetic philosophers like Mr. Pickwick to contemplate but without a vestige of truth in the portraits. There had been, however, a member of the profession now extinct as far as his orbit extended though he fancied he survived in rural parts—that was the apothecary of his childhood, who was really a good medicine man, as the Indians express it, as he not merely recommended but compounded his medicine himself. But he had changed his name, given up the good old name of apothecary, and become a general practitioner. You never read of a general practitioner in "Romeo and Juliet," and in Pendennis you may find the older hero who perhaps gave us too much medicine, and perhaps we did not take it all. "I still feel his warm hand resting on my tremulous pulse," said his lordship, and turned to the more serious part of his subject. Medicine, he said, was the noblest secular career in the world—the one which tries wherever it goes, unselfishly, willingly, earnestly, to give comfort and alleviation to all with whom it deals. It was the noblest profession because it was a forlorn hope of humanity; a forlorn hope because it could never hope to conquer in the long run, yet it never despaired, and was always seeking new inspiration and new strength for the battle which could only have one termination. It was a forlorn hope for it combated the reptile of disease, from which, though you successively cut off a limb, like the fabled dragon of old another sprang up to take its place; a forlorn hope because when you had conquered one form of disease another form, such as sleeping sickness, was sure to spring up; a forlorn hope because all day long and every minute of your career you had to be fighting with the angel of death, which must inevitably defeat you in the end. Did that seem a gloomy view of the profession? He thought not, because it was rare to find a life which could be spent in the complete conquest of obstacles, but in your career you were fighting the most heroic fight going on in the world, and fighting it not for selfish interests, but in the cause of humanity itself. Take the great names of history—the Cæsars, Napoleons, Wellingtons—before whom all bend the knee—they all, selfishly or not, had been banes and injuries to generations. Take, then, one single name from your profession—take the name of Lister, and balance against that all the historical figures who have devoted their lives to conquest and bloodshed. Put them all on one side of the balance and that of Lister on the other, and would any intelligent human being hesitate as to which side it was to which the universal gratitude of mankind was due? You should then be proud to join in this great crusade in this army of compassion and alleviation. And where can you better enlist than in this great hospital—the first in the world? "At my age one is chary about employing the word first, but it is, let me say so, the first in the world."

The next day Lord Roseberry was again in the position which suits him so well. He opened the Congress of the Universities in the British Empire and dilated on their growth and expansion since 1830, when England had two and Scotland four, though the last are linked in couples, making the balance even. At the same time Scotland may claim a greater zeal in educational matters. To-day no less than fifty-three universities are in congress. Lord Roseberry regarded them as "machines for producing men; the best kind of machines for producing the best kind of men, who may help to preserve our empire."

In the Obstetrical Section (R. S. M.) Dr. Willett related a case of a rather rare condition obstructing the termination of labor. The head was brought down to the outlet, but the shoulders were detained above by a thick retraction ring which completely encircled the lower part of the neck. The child was dead, so the head was perforated, a cranioclast firmly fixed and an eight-pound weight applied to its handle by a towel. Morphia (½ gr.) was injected to relieve spasm, and the patient slept for three hours. On waking delivery quickly followed a few pains, and the placenta came naturally. A hot intrauterine douche was given, and it was found the ring had disappeared. Some septic symptoms complicated convalescence, but the patient left hospital after a fortnight. Dr. Willett thought the case an ideal one for continuous traction by weight—dead child and mother's state not urgent.

Dr. Herbert Williamson mentioned an allied case of a ring detaining the shoulders. Delivery was effected by steady traction with forceps, to which the ring yielded after fifteen minutes. Some hemorrhage followed, and the placenta was expressed, but the bleeding continued. Examination showed a tear in the vaginal vault extending through the cervix and lower wall of uterus. The rent was sutured with catgut and the broad ligament lightly plugged with gauze (removed in twenty-four hours). A good recovery followed.

The report of the museum committee of the Royal College of Surgeons is issued. Upwards of 1,000 specimens have been added during the year. The most interesting addition is the collection presented by the executors of Lord Lister, comprising instruments, many designed and used or modified by him. These are to be kept as a separate collection, and can not fail to be an attraction in the future. The Royal Society of Medicine has presented a collection of historical interest, being instruments that have been used in midwifery. Another collection was presented by Mr. Penrose Williams of Bridgewater, and contains many surgical instruments of the eighteenth and nineteenth centuries. A medicolegal collection has been begun, and specimens are coming in.

The insurance act is still troubling us. The Liverpool practitioners have signed resignations to various clubs and made arrangements for attending patients. Meantime about 200 Birmingham medical men have given notice that they will terminate their contracts with the clubs. The inquiry undertaken by Sir William Plender for the insurance commissioners into the remuneration of

medical men in six selected towns is beset with difficulties. The auditor is required to show separately all sorts of items which go to make up the practice, such as visits, medicines, certificates, reports. How many doctors keep a set of books from which such matters can be extracted? No auditor, I think, would be able to apportion the items without the doctor's attendance all the time and supplementing the figures by his memory of each case.

Questions were asked in the House last night, but the government, as usual, only shuffled.

The King's visit to Bristol last week was mainly for the purpose of opening the new surgical department of the King Edward VII Memorial Infirmary. This has cost between £70,000 and £80,000, and is only the first part of the scheme, which will run to about £200,000. It is, however, as it stands, complete in itself. It is intended when the whole is carried out to transfer the old infirmary to the new site, where the grounds will have about two acres of garden. The old Bristol Infirmary is the largest hospital in the west of England, and perhaps the oldest in the kingdom. It was founded in 1735, and contains 270 beds, but extension is imperative, and with the new hospital 180 will be added. The sojourn of the King and Queen was short, but their majesties took part in various ceremonies, including the reception of five addresses, to which the King replied, and the old city turned out and greeted them with enthusiasm as they passed through the miles of decorated streets.

Dr. William Murrell, physician to the Westminster Hospital, and lecturer on medicine in the school, died suddenly on the 28th ult. He was, an authority on materia medica and therapeutics, on which he lectured for many years, and served as examiner on this subject at the London Royal Colleges and also at the universities of Edinburgh, Aberdeen, and Glasgow. His "What to Do in Cases of Poisoning" ran through eleven editions. He edited Fothergill's "Practitioners' Handbook of Treatment," and was a contributor of many papers to the societies and journals. He qualified in 1874-5, took the Brussels degree in 1879, and was elected F.R.C.P. Lond. in 1883. He was a laureate of the French Academy of Medicine and fellow of the Philadelphia Medico-Chirurgical College.

Lt.-Col. F. E. McFarland died on June 24 after a long and honorable career, for the first twenty years in the Army Medical Department (serving chiefly in India), and after that in Belfast, where he was elected by his brethren president of the Ulster Medical Society, and was consulting physician of the Women and Children's Hospital. He qualified at the two Royal Colleges of Dublin as long ago as 1858.

Fleet-Surgeon Frederick Walter Stericker, R.N., who only recently retired from the Naval Medical Service, died on July 1 at the age of 51.

THE PLAGUE IN HAVANA.

(From Our Regular Correspondent.)

HAVANA, July 14, 1912.

WE learned of the existence of plague in Porto Rico about three weeks ago. Quarantine against Porto Rican ports was established and at the same time the hunt for dead rats was begun in the neighborhood of the docks where it was said that an unusual mortality among those rodents had been observed. The bacteriological examination of the few rats then collected, however, failed to show the presence of the pest bacillus; some gave sterile cultures, showing that they had been killed by poison, probably arsenic. On the evening of July 4 the first suspicious case was recorded in a man with inguinal adenitis and rather severe general symptoms. He was sent to one of the Emergency Stations and from there to Hospital No. One, which is a general hospital of about 500 beds, the wards being arranged in separate pavilions. The man was transferred to Las Animas Hospital for Infectious Diseases the same evening and smears and cultures were made from fluid extracted from the bubo. The Board of Infectious Diseases visited the case next morning and examined the smears, which showed the presence of a few bipolar stained bacilli, very much like the plague bacillus. The Board deferred the diagnosis until the following day so as to allow time for biological tests that would eliminate the possibility of glanders, since the man had worked in a stable, and also to carry out a thorough examination of the cultures made. The result, by unanimous opinion, was that the case, as suspected originally, undoubtedly was one of plague, and so it was officially declared on the morning of the 6th. This man has been doing well and at this moment is out of all danger, but, of course, the full period of quarantine will pass before he will be allowed to be at large.

A second confirmed case was officially declared on the morning of the 12th, in a man that came from the infected zone, the diagnosis being made after the patient died, but it being declared suspicious from the second day of his illness.

The sanitary department had been active all this time and not only the entire block where the case of plague originated was disinfected but also many other blocks of buildings, where it is surmised that other cases have taken place during the last month, were also fumigated. These cases did not come under the notice of the sanitary authorities until many days after the death of the patients, and it is only by a process of elimination and deduction that it is believed they were cases of plague.

Whole blocks of houses are subjected to vigorous fumigation with sulphur and formaldehyde and at the same time all rat holes are stopped up with cement and broken glass; the floors are flooded with insecticide solutions to destroy fleas and vermin, and everywhere, even outside the supposedly infected zone, the people are engaged in the wholesale trapping and poisoning of rats, since a bonus of five cents each is paid for them when delivered at any of the various stations, whether dead or alive. Popular instructions have been widely distributed all over the city, giving easily applicable preventive measures. Every patient admitted to any of the five hospitals in this city is carefully investigated and all cases of "adentitis" are considered suspicious until the Board of Infectious Diseases passes upon them. The cooperation of the people is a fact that the sanitary authorities value highly; fortunately, the previous training obtained during the yellow fever campaign has been of the greatest aid and the authorities have certainly obtained the confidence of the public at large. This is made manifest by the faithful observance of all measures that have been undertaken. The directing personnel is one which has been engaged for many years in sanitary work, dating back to the Spanish war, and although without practical experience with bubonic plague it

is perfectly conversant with the work at hand. Dr. J. Guiteras is the Director of Public Health and Dr. A. Agramonte, chairman of the Board of Infectious Diseases. Dr. M. Lobredo is chief of the Research Laboratory, where the bacteriological work is carried out, and Dr. Lopez del Valle, the Health Officer of Havana, has been in charge since General Wood's time.

One of the most remarkable circumstances in connection with this importation of the plague into Havana has been the absence of the infection among the rats; at least it has been impossible so far to demonstrate it in spite of the most earnest search which is being made for the infected animals. Everything relating to the extension of the process, the progress of disinfection, the necessary measures to be adopted, etc., is widely published for the information of all, and absolutely nothing is kept from the public which is thereby rendered more confident and more composed in the presence of the threatened danger.

THE EARLY DIAGNOSIS OF UTERINE CANCER.

To the Editor of Medical Record:

Sir:—In elucidation of the method now being investigated for the earlier diagnosis of uterine cancer by means of the curve of past health, it must be recognized that, occasionally, control cases (breast cancer, uterine fibroid, etc.) will present a history of greatest weight in the incipient stage, but the maximum weight curve will not be coincident with maximum health and strength curves. When internal pelvic strain results in a want of equilibrium of nerve forces the deficiency shows itself in weakened action on the part of the cerebrospinal system, of the sympathetic system, or of both. Should the cerebrospinal only be affected we have some weakening of muscle, causing abnormal conditions of nerve, obstructed action, and probably in turn sequential cancer. Such a woman might, however, remain in moderately good health and even reach her maximum weight. When both maximum weight, health, and strength are reported in the incipient stage of a control case, this maximum weight, health, and strength is notably below *perfect* health.

On the other hand, when a woman with organic disorders becomes the victim of uterine cancer, there is not as rapid a return to perfect health as in the merely functional cases. In the beginning of the incipient stage, therefore, her health curve would not correspond with the plane of perfect health. Correcting the position of the uterus either by treatment or operation should liberate nerve force, and as a result cure or benefit many cases of the functional nervous troubles, or even some insanities. Notwithstanding the fact that insane women are as subject to ordinary pelvic disorders as are women in general, uterine cancer is found but seldom among them, probably because the functionally deranged woman will have recovered her mental or nervous equilibrium several years before the recognized advent of cancer of the uterus. Cervical tears become the site of malignant disease when the uterus is displaced in such a manner and extent as to injure nervous structure controlling the area of the uterus embracing the cervical tear, cell proliferation taking place in that particular portion of the affected nerve area which has already been injured. When displacement of the uterus is *not* such as to cripple the nerve area embracing the tear, then the tear will not become the site of a malignant growth. Failure to perform a sufficiently extensive operation in early cases of uterine cancer may account for the unlooked-for fatal termination, while cases presenting an unfavorable prognosis may prove most happily disappointing owing to an enforced wide excision, *provided* that such wide excision embraces the complete nerve area from point of injury. Should this point of injury be so situated that filaments beyond the confines of the uterus are involved complications will result.

At a meeting recently held at the College of Physicians of Philadelphia, through the courtesy of the hall committee, it was decided to collect data in answer to the following questions, the object being to gather data from which to tabulate weight, strength, and health diagrams.

Diagnosis? 1. Age of patient upon diagnosis of disease? 2. Age of patient at time of maximum weight? (a) If about as heavy at any other time in her life; at about what age? 3. Age of patient at time of greatest strength and endurance? (a) If about as strong at any other time in her life; at about what age? 4. Age of patient when least subject, if at all, to aches, pains, or ailments? (a) If in about as good health at any other time in her life, at about what age?

Contributions will include not only data from uterine cancer cases but also records of any of its controls, *i. e.*, all forms of cancer in woman, and all uterine diseases other than cancer.

Philadelphia. E. Atlee.

THE DANGER OF OVERLOOKING URETHRAL CHANCRES.

To the Editor of the Medical Record:

Sir:—A case seen by me recently induces me to pen this note. The admonition to bear urethral chancres in mind, it seems, needs constant iteration and reiteration. The patient stated to me that he had been treated for gonorrhea for the last eight weeks. An indurated spot in the urethra, the gaping meatus, and the extremely abundant seropurulent discharge made me suspicious of the diagnosis of gonorrhea. The large indurated, indolent inguinal swellings made the diagnosis still more doubtful. An examination of the patient's body made the diagnosis perfectly clear. It was so clear that any tyro could have made the correct diagnosis.

Had the doctor examined the patient's naked body once, the diagnosis would have been as clear to him as to anybody, but he could not get away from his preconceived idea and once-decided-upon diagnosis. He started to treat the patient for gonorrhea and it didn't come to his mind that it could be anything else. It is hard for a person to change the direction of the current of his own thoughts. It is due to this that changing doctors is sometimes so beneficial for the patient. It is quite probable that the doctor would have treated that patient for many months, or weeks at least, without seeing any other part of his body but the penis. Only abundant mucous patches or an eruption on the face might have made him ponder.

And all this is simply due to physicians not being sufficiently familiar with the fact that chancres of the meatus, and even of the deeper urethra, are not at all such rare occurrences. Nor are chancroids within the urethra so rare. And for the welfare of

our patients we must always be on guard and bear in mind that a urethral discharge is not always due to the gonococcus of Neisser. The streptococcus, the bacillus of Ducrey, and the spirochete of Schaudinn are also important factors in causing a running from the urethra.

7. A Case of Chronic Infective Endocarditis with Ulceration of Chordæ Tendineæ. F. W. Palfrey and J. B. Ayer.

1. **Cancer of the Uterus.**—F. Cobb states that whenever opportunity offered he has done the radical operation for cancer of the uterus according to Wertheim's method, with wide dissection of the pelvis and ureters and removal of as much as possible of the parametrium, and although the number of his cases has been small, over 50 per cent. of them have been alive and well for more than five years since the operation. The question arises: "What is an operable case?" If the entire pelvis is filled with a hard mass, if the uterus is fixed and if the vagina is indurated well down toward the vulva, there is no doubt but that such a case is inoperable, but in many cases no bimanual examination, with or without an anesthetic, can determine positively that the case is not one for radical operation; fixation of the uterus, and the presence of indurated masses in one or both broad ligaments, may be due purely to inflammatory tissue, adhesions, pus tubes or cysts. A palliative operation ought to be done whenever possible to stop hemorrhage and offensive discharge, to prolong life, and always to promote mental comfort and happiness. A thorough palliative operation, with the curette and actual cautery, will prolong life. The usual early symptom of uterine cancer is irregular hemorrhage. The most important features of the operation in the author's experience are as follows: the preliminary preparation of the patient and anesthesia, prevention of peritoneal infection from the growth itself, dissection of the ureters, removal of the glands, hemostasis, drainage, and the after treatment.

4. **Hopeful Aspects of Cancer of the Uterus.**—W. P. Graves states that cancer of the body of the uterus is a surgical disease of comparatively little danger, giving early warning of its presence and being easily operable and extremely favorable as to non-recurrence. Cancer of the cervix, though insidious in onset and dreadful in its later stages if neglected, is entirely operable in its early stages and if operated on early is favorable as to non-recurrence. There is need of better education of medical students in the pathology and clinical diagnosis of the disease. The surgical treatment of cancer of the uterus is par excellence Wertheim's extended abdominal operation.

5. **A New Conception of Anaphylaxis.**—W. M. Barton advances the theory that anaphylaxis consists in the formation of proteolytic ferments, or enzymes, in certain tissues of the body. It is assumed that the structures chiefly involved in elaborating these enzymes are the epithelial and perhaps also the endothelial tissues. These enzymes, or ferments, endow the cells in which they are formed, or the fluids into which they are excreted, with an increased capacity of digesting foreign proteid. The symptoms of anaphylaxis are partly reflex results of the tremendous physiological aberration which this vicarious digestion induces, and partly the result of the products themselves, acting toxically upon the cells of the central nervous system and other organs. The first ingestion of a foreign proteid induces the formation of the enzymes. These remain stored up in the cells where they are formed, or circulate in the fluids of the body until the next ingestion of the foreign proteid. This can only occur in small amounts, under conditions in nature, amounts so small in fact that their digestion and destruction are brought about without direct or indirect effects upon the organism as a whole, and particularly its vital parts. But under the conditions of an anaphylactic experiment, a quantity of the proteid is absorbed sufficient to stimulate the formation of digestive enzymes in all or many of the epithelial structures of the body, and the second injection of proteid supplies a sufficient quantity to be distributed throughout the organism, so that its digestion is undertaken simultaneously by countless epithelial cells, and the symptoms of anaphylaxis are produced.

1. **Direct Treatment of Syphilis of the Nervous System.**—H. F. Swift and A. W. M. Ellis state that the spirochetes seem to have a special predilection for the lymph spaces. The subarachnoid space may be considered the great lymphatic sheath of the central nervous system. The portion of the latter which is most frequently involved in syphilis is the base of the brain between the peduncles and optic chiasm. This is the site of one of the large subarachnoid cisterns. Because of the peculiar anatomical conditions in syphilitic meningoarteritis, the treatment by ordinary means is quite difficult. This is probably due to the fact that there is an imperfect application of the therapeutic agent through the blood stream. The most intense process is bathed only by the spinal fluid, into which there is little, if any, excretion of curative agents. Even so highly diffusible a drug as potassium iodide is not normally excreted into the spinal fluid. Basing their method upon the known fact that the blood serum of treated syphilitics has curative powers, the authors have been studying the therapeutic effect of such serums when injected intraspinously into patients with tabes and other syphilitic affections of the central nervous system. At first the serum was obtained by withdrawing blood from the patient on the day following a salvarsan treatment. Gradually the time has been shortened so that now the blood is withdrawn an hour after the intravenous injection of salvarsan or neosalvarsan. The results in some instances of this method of treatment are as follows: Four tabetics had received repeated intravenous injections of salvarsan, in addition to mercurial treatment, with resulting symptomatic improvement and reduction in the cell count in the spinal fluid. Upon instituting intraspinous injections of their own serum obtained shortly after the intravenous injections of salvarsan, the cell count promptly fell to normal, the globulin decreased in amount much more rapidly than previously, and in two of the patients the Wassermann reaction in the spinal fluid became negative, even when 0.5 c.c. of fluid was used. While the series of cases reported is small, the authors feel that the results up to the present are of sufficient value to warrant a continuation of the work and its institution on a larger scale. The best results can be obtained from the intravenous

treatment with salvarsan or neosalvarsan, combined with intraspinous injections of the patient's own serum, possibly with the addition of small amounts of neosalvarsan.

2. **Indications for Removal of the Faucial Tonsils.**—H. Hays, as a result of his studies, has come to the following conclusions: The tonsil has a definite function in early childhood. Tonsils should not be removed unless there is some especial indication before four years of age. Small, buried tonsils associated with enlarged cervical glands should always be completely removed unless some definite cause is found for the condition. Tuberculosis is often found to be of tonsillar origin. One of the most important points to be considered in judging whether a tonsil should be removed or not is the size of that tonsil in relation to the individual throat. All tonsils, large or small, which seriously interfere with respiration, should be removed. Many local pathological conditions are caused by diseased tonsils. Many cases of middle ear catarrh can be prevented by removal of the tonsils. There is a distinct relationship between the tonsils and many general diseases. The promiscuous removal of the tonsils of children without the finding of some associated pathological condition is not advisable.

4. **The Physical Welfare of Policyholders.**—By E. L. Fisk. (See page 127.)

6. **The X-Ray Treatment of Acne.**—M. K. Fisher describes the method that he employs as follows: The patient is placed in the recumbent posture; the hair, eyelashes, and eyes, and if a man, the moustache, are covered with lead foil; each side of the face is treated separately, as it is difficult to get an even distribution of the rays if full faced exposure is made, especially if there happen to be a number of lesions back of the malar eminences or near the angle of the jaw; a tube of low vacuum is used, held in a protective leaden glass shield, eight to ten inches above the region over which the exposure is to be made; the rays, which are filtered through sole leather, should allow the passage of three-fourths to one milliampere of current through the secondary circuit, or, if a radiometer or milliamperemeter cannot be employed, about the radiance that in a darkened room will show as a faint yellowish green light; each side of the face receives an exposure of six to ten minutes, depending on the amount of inflammatory reaction that is present, those cases where there is already present considerable redness not being treated so strenuously, while in cases in which there is much induration the more prolonged exposures are given. Treatments are given twice a week, although after a time the séances may be reduced to once a week. If given more frequently, the treatment may produce a burn, and the author has never found it necessary, or even advisable, as Stelwagon and others have recommended, to push the treatment to the extent of producing an erythema, and then discontinuing treatment until the redness has disappeared. For the first two or three weeks after commencing treatment little change can be noted in the disease; gradually the redness is seen to become less pronounced and the lesions almost imperceptibly to fade; the indurated areas decrease in size, and in the pustular form of acne there is less tendency for suppuration to result. One of the first effects noted is the disappearance of the oily seborrhea, which, as Sabouraud asserts, always accompanies the acne.

3. **The Resistance of the Patient as a Guide to Operative Procedure.**—W. B. Chase discusses first the subject of inherited longevity. He states that, other things being equal, it is safe to assume that the inherited tendencies noted in families and in individuals offer evidence which the operator should summon to his aid in all cases, particularly in serious emergencies, in determining the probable status of the patient, with reference to any operation which cannot be tested by other standards. If the history of the patient shows recovery from one or more previous attacks of serious illness, it increases the chances of recovery after grave operation. Recovery after serious accidents also serves as an indication of the patient's power of resistance. Of similar value is the recovery from previous surgical operations. The more serious and the more frequent the operations, the more valuable as guides do they become under new surgical complications. The present health of the individual must be taken into consideration. This implies a careful inquiry into the condition of the nervous, circulatory, secretory, and excretory organs of the body, with an appreciation of organic or functional derangements as accessories—important in the final analysis of cases which make for the resistance or want of resistance in the individual case. The relation of the resistance of the patient to the time taken for an operation, the shock incident to it and the anesthetic employed are of the highest importance and difficult to determine in advance. The time of every operation should be the least possible compatible with thoroughness.

4. **Hysterotomy.**—J. B. Deaver states that his experience with the few cases he has operated on has been so satisfactory as to warrant bringing this operation up for consideration, in the belief that it should be kept in mind and employed in certain selected cases more often than is now the case. He wishes especially to urge that placenta prævia must be considered an indication for hysterotomy which is to be given the preference over any other method of delivery. In the severe stages toxemias of pregnancy it is to be seriously considered as a rival of less radical measures. In certain myomatous uteri and in the presence of pedunculated intrauterine growths or endometrial changes one may on occasion find it of great help in relieving the patients most expeditiously of their symptoms. The chief contraindication is the presence of intrauterine infection, either demonstrated or strongly suspected. The author would not at the present time open a uterus in the interior of which he feared to find infection. If this precaution is observed the operation is one of extreme simplicity and low mortality, but should be undertaken only by an experienced surgeon who is a master of intraabdominal technique.

7. **Diseases of the Fallopian Tubes.**—H. J. Boldt discusses the infections of the Fallopian tubes and their consequences. Gonorrheal salpingitis can be credited with most tubal pregnancies, and it may also be the cause of menstrual disorders, most commonly menorrhagia, as exacerbations are apt to occur about the monthly period. There is no pain characteristic of tubal inflammation, but it may occur in various ways. Backache is a prominent symptom, usually accompanied by pain in the lower abdomen. Neurasthenia is not a rare occurrence. In case

a rupture of a distended tube takes place intraperitoneally the symptoms vary according to the virulence of the tubal contents. The accident is a serious one, and when, in a known case of pyosalpinx, sudden collapse occurs, surgical intervention is called for. The diagnosis of these cases calls for palpation, and this can only be done by the bimanual method. The position of an inflamed Fallopian tube may be abnormal and the latter may even simulate a tumor. To make a diagnosis of tuberculous salpingitis other evidence of tuberculous infection is necessary. It is not always easy to recognize the contents of the tube by palpation. The doughy sensation of pyosalpinx to the examining finger contrasted with the elastic feeling of the hydrosalpinx is the most reliable symptom in differentiating the two. Hematosalpinx, not due to tubal gestation or genital atresias, cannot be diagnosed with certainty except by puncture, which is not desirable. A tubal gestation, if uninterrupted, is best indicated by the other changes attending pregnancy, but some cases may be very puzzling, as are one or two reported. The prognosis of tubal disease, except in malignant cases, is generally good as far as life is concerned. The restoration to health, however, depends on circumstances. Boldt believes the majority of acute gonorrheal cases will recover if properly treated and if subsequent infection is prevented. If the fimbriated extremities have been closed and if the tubes have become more distended, the prognosis of a cure from a pathological point of view is out of the question. The acute gonorrheal conditions during the puerperal state have a serious aspect, but if proper treatment is used most of these cases recover. The main principle of treatment is complete avoidance of sexual excitement with physical rest and hygiene; surgical operations should not be too hastily employed in the first attacks. Local treatment with hot douches, ichthyol, etc., are useful. In case of surgical intervention the author advises a large incision and vaginal section. For abdominal operations he prefers the longitudinal incision. Every factor should be carefully weighed before surgical measures are employed, and radical operations should be avoided in acute pelvic peritonitis from tubal inflammation. The curette should not be used in gonorrheal cases.

8. Superfluous Hair.—H. C. Baum describes his method of employing electrolysis in the treatment of this condition. The skin is mopped with absolute alcohol which macerates the thickened sebum, is to some extent germicidal and which is very efficient in obtunding sensation. The needle is introduced without force till it reaches the bottom of the follicle or meets resistance. The current is then passed until the follicle whitens or until bubbles serve to mark the site of the hair follicle. The hair is epilated and the needle is returned through the vacated follicle, until it rests on the papilla. Enough electrolysis is then employed to destroy the papilla. After the hair is pulled out and the needle is placed directly on the papilla, much less tissue is cauterized than if the papilla were destroyed while surrounded by the hair bulb. Meanwhile the application of absolute alcohol goes on. The author uses a rounded olive-pointed needle and a special needle holder. The positive pole is grasped by the patient's hand and a current from one-third to one milliampere, measured, not guessed, is used. This method is painless, and the results are better than with a stronger current. The La Clanche battery is used. The smaller the diameter of the needle the nicer the technique and the better the result. Scarring to any extent is not necessary. The majority of these cases occur in unmarried women; the author has seen it cured by marriage or the relief of dysmenorrhea. As toxemias destroy hair on the top of the head, so they seem responsible for the overgrowth of hair on the face. Indicanuria is present in many of the cases, and with improved metabolism the tendency toward the growth of superfluous hair is modified or overcome. In diabetics it is not unusual to see the growth increase on the face, while thinning on the scalp is the rule. Overworked spinster school teachers furnish the largest quota of the author's cases, and it is manifestly not always possible to remove the cause, but many cases are susceptible to varying degrees of relief without resort to electrolysis.

1. The Pathology of Immunity.—L. S. Dudgeon states that the exudate from an infected focus may be more suitable for pathological investigation than the blood serum of the patient. The exudate may contain either immune body, aggressin, or complement, or all three together in the same exudate, or only the immune body and aggressin. The aggressins are thermo-stable in the vast majority of cases, and some exudates may contain specific substances which resist boiling, while the common inhibitory bodies are usually unaffected by temperatures falling between 55° C. to 60° C. The effect on phagocytosis is due to an interaction of the blood serum and exudate. There is also evidence that the exudates may act directly on the leucocytes. It would seem that the most thermo-stable substances in inflammatory exudates are really bacterial extracts which have a specific inhibitory effect on phagocytosis and which are able to establish immunity, while the substances which resist a temperature of 60° C. for twenty minutes, but are destroyed by boiling, are also actively aggressive, and those exudates which are completely thermo-labile are never aggressive. In experiments on the injection of certain rabbit exudates into rabbits, the most striking phenomenon which presents itself is the leucocytic depression. The leucocytes may fall in half an hour from 10,000 to 1,000 per c.mm. or even less, and the polynuclear decrease is almost constant. Lymphocytic leucopenia is also usually present.

2. Moot Points in the Pathology and Clinical History of Pneumonia.—P. Kidd discusses the varieties of lobar pneumonia. The "Friedländer" pneumonia appears to have attracted more attention in Germany than elsewhere. Pneumonia of lobar dimensions may be caused by the pneumobacillus alone, as Weichselbaum has always maintained. The typical bacilli may be found in the sputum and in the blood during life, and they have been present in the contents of a pulmonary abscess incised by the surgeon. The appearances of the consolidated lung are not always fully described, but where a detailed account is given the hepatization is said to be gray or blackish-gray and not granular. The contents of the alveoli consist mainly of desquamated epithelial cells and bacilli, with very little fibrin and with less leucocytes and red corpuscles than in pneumococcal cases. The tendency to necrosis and suppuration is remarkable, con-

trasting strongly in this respect with pneumococcal pneumonia. Toeniessen states that suppurative softening occurred in nearly one-half of all the cases recorded. In many cases where gangrene and abscess occurred the pneumobacillus alone was present. With regard to the clinical aspects, most writers are agreed that the course is severe and the mortality is terribly high. Apelt goes so far as to say that he believes that only one recovery has been recorded, viz., one in which Lenhartz drained a gangrenous cavity in the lung. The accounts of streptococcal pneumonia are scarce. Weichselbaum refers to cases of this description, without giving details, and states that streptococcal pneumonia is at times indistinguishable from typical lobar pneumonia, and also that in some pneumonias clinically regarded as anomalous cocci are found closely resembling *Streptococcus pyogenes*, both microscopically and culturally. In Lippmann's monograph reference is made to researches on certain affections styled "pulmonary congestion" by French authors which in England are regarded as varieties of pneumonia. These include "maladie de Woillez," an abortive form of pneumonia, pleuropulmonary congestion of Potain, a variety of pleuropneumonia, and the splenopneumonia of Grancher. The term "splenopneumonia" was introduced by Grancher in 1883 to denote "a variety of subacute pneumonia which simulates pleurisy with moderate effusion." Grancher in his original account described three cases of this complaint. In these the onset was attended with pleuritic pains and shivering. The physical signs indicated, in his opinon, pulmonary congestion and a small pleural effusion, the physical signs being dullness on percussion, diminished vocal fremitus, weak blowing breathing and bronchoegophony. All the cases made a slow recovery in the course of some weeks. Grancher believes that these cases are examples of splenization in which the solid lung is red and smooth.

3. **The Lungs and Genitalia of Tuberculous Women.**—H. von Bardeleben states that genital tuberculosis as a rule arises from pulmonary tuberculosis. On the other hand, clinical experience teaches that the prognosis of pulmonary tuberculosis becomes much worse with the complication of genital tuberculosis. Thus genital tuberculosis is usually combined with severe pulmonary tuberculosis in dissected cases, while an early removal of the genital tuberculosis, by means of an operation, often makes it possible to cure a newly kindled pulmonary tuberculosis. In pregnancy the placenta or the placenta uterina is often the cardinal point of this action and reaction: (a) It often offers a harbor to tubercle bacilli circulating through the blood, from which at every opportunity, especially at the separation of the placenta, the bacilli can be again mobilized (childbed). (b) And, therefore, the greater the chances may be of this happening in cases of active, manifest pulmonary tuberculosis, the more injurious are the effects of the pregnancy (90 per cent.), whereas the slighter the chances are of bacilli circulating in the blood the more seldom does the pulmonary tuberculosis become worse (15 per cent.). In the same manner is proved the agreement of the results of anatomical research with regard to the placenta and therapeutic interventions. (a) Artificial abortion produces really good results only in those cases in which tubercle bacilli are practically never found in the placenta (simple catarrh of the lungs till the fourth month of pregnancy). It produces, on the other hand, unsatisfactory results in cases in which altogether 70 to 80 per cent. placental tuberculosis is to be found (simple affection of the lungs with strongly developed placenta after the fourth month of pregnancy), or more extensive or intensive lung tuberculosis, also in the early months of pregnancy. (b) The results are just as good in either indication, if, instead of merely removing the embryo, the simultaneous excision of the placenta uterina is made.

1. **The Pathology of Immunity.**—L. S. Dudgeon states that filtered pneumococcus exudate prepared from rabbits and injected into mice together with the pneumococcus causes a more rapidly fatal result than when the pneumococcus alone is injected, but this aggravated action of the exudate is similar to the results obtained by Cole and Smirnow, who found that mice injected intraperitoneally with the pneumococcus and normal rabbit or pigeon serum died more rapidly than control mice which received the pneumococcus only. Fifteen minutes after intraperitoneal inoculation of bacteria—pathogenic or non-pathogenic—an exudate appears which contains an abundance of complement and a certain amount of opsonin, although much less than that of the animal's blood serum. It is a fact of interest that the exudate which collects in the peritoneum of the immunized animals at the end of one hour may have a greater or equal power to excite phagocytosis than the blood serum of the animal, while control animals treated in a similar manner do not show such active phagocytosis, and there is evidence that this high degree of phagocytosis is specific. There is also active complement present in the exudate in each case. Active local immunity as a result of intraperitoneal immunization must obviously be of great service to an animal infected in the immune area, but it is not a constant result. All workers on the subject of aggressins are agreed that exudates formed within the animal body from bacterial infection need not necessarily be aggressive. If exudates contain a full supply of active complement and opsonin they seldom contain much aggressin; in fact, the action of such exudates is usually in direct contrast to that of an aggressive fluid. It is especially in exudates derived from animals suffering from severe bacterial infection or dying from lesions of great severity that one must look for these so-called aggressins. It can be shown both *in vitro* and *in vivo* that the action of aggressive exudates is not necessarily specific and various exudates and blood sera may produce an aggressive effect apart from any question of specificity.

2. **Vascular Lesion in Middle Meningeal Hemorrhage.**—F. W. Jones concludes from his investigations that the anatomical condition of the vascular channels of the dura mater is as a rule not appreciated, and that an attentive examination of these channels at post-mortem inquiries held on these cases is very desirable. From a purely anatomical point of view there is great probability that, in cases not caused by excessive violence, the sinus is far more likely to be injured than the artery. In those cases—especially common in children—in which the violence is trivial, and no fracture is caused, the cerebral compression and ensuing death are due to the development of a hematoma beneath the vascular dura mater strictly comparable to the well-known hematomata developed beneath the vascular pericranium. In the twelve bleeding points yielded by three fatal cases which have been examined in serial sections, the blood had invariably escaped from a laceration of the venous sinus, and in no instance could an arterial lesion be found. From the published accounts of the bleeding encountered at operations undertaken for the relief of symptoms it would seem that in the majority of such cases the blood was

issuing from a ruptured venous sinus rather than from the artery. In the cases examined there is evidence that following upon the initial wound of the sinus wall venous blood is extravasated between the dura mater and the bone, and that continuance of the bleeding causes a continuance of the stripping of the membrane from the bone with the development of an accumulating laminated extradural clot. Probably only in rare cases—and especially those in which excessive violence has produced linear or depressed fractures—is the middle meningeal artery actually wounded. Dangerous, or difficultly controlled, hemorrhage is not the rule at operations undertaken for the relief of this condition; in children especially any cranial injury, however trivial, should be regarded as the possible cause of a dangerous, and possibly fatal. dural hematoma, and operation for evacuation of the clot and relief of pressure symptoms should always be undertaken regardless of subsequent hemorrhage, which, being usually venous, is easily brought under control.

3. **A Case of Angina Abdominis.**—W. K. Hunter reports the case of a man aged 56 years who 18 months before he was admitted to the hospital began to suffer from attacks of pain in the epigastrium. During the month the patient was under observation he had paroxysms of pain every day, at intervals of 15 to 20 minutes and lasting about one minute. The pain was very severe and the attacks seemed to be too frequent and to have occurred over too long a period of time to be attributed to gallstones. During the spasms of pain the respiration became quickened and the face rather cyanosed. There was marked cardiac arrhythmia; the heart sounds were indistinct, but there was no murmur. The radials were atheromatous and there were signs of hypostasis at the base of both lungs. The feet and legs were edematous. The signs of myocardial failure persisted and became more marked. The patient died at last with all the signs of heart failure. Autopsy revealed a typical myocarditis, a widespread patchy atheroma of the aorta and sclerosis of the coronary arteries. The case corresponded very closely in its clinical as well as in its pathological aspect to those cases described by Huchard under the phrase *"angine à forme pseudogastralgique."*

6. **The Examination of Diphtheria Specimens.**—C. Ponder describes his method of staining smears as follows: A film is made on a cover glass and fixed in the usual way. The stain has the following composition: Toluidin blue (Grubler), 0.02 gram; glacial acetic acid, 1 c.c.; absolute alcohol, 2 c.c.; distilled water to 100 c.c. A small quantity of the fluid having this composition is taken up with a platinum loop and dabbed and spread on the film; the cover slip is then turned over and mounted as a "hanging-drop" preparation and it is now ready for immediate examination with the 1/12 objective in oil. The examination should be made with a strong artificial light; daylight is not suitable. The author is accustomed to use a 16 candlepower frosted electric bulb at a distance of from 6 to 8 inches from the mirror. The influence of the thin layer of blue fluid is in the direction of correcting the yellowness of the artificial light. Films should be freshly prepared and thinly spread. Experience soon shows the right amount of stain to place on the film; the drop should be rather shallow—not too deep so that its blue shade cuts off too much of the light, nor so little in amount that there is not sufficient stain for the organisms to become fully saturated. The cells take up the stain practically instantaneously, and the preparation may be examined at once or any time during the next 3 or 4 hours; after that there is a tendency for overstaining to take place. The toluidin hanging-drop method here described differentiates the diphtheria bacillus from the other organisms in the same film more clearly than any other method, because while giving a double stain—blue bacilli with red granules—it shows the minute structure of all organisms very distinctly. It has a special value in demonstrating the organism in a direct smear without preliminary cultivation, as by this means, in a large proportion of acute cases of the disease, a much earlier diagnosis may be made. It also demonstrates the organisms of Vincent's angina if present. It is extraordinarily simple and rapidly carried out, so that in a laboratory where a large number of specimens require to be examined a great saving of time results.

1. **Prurigo, Pruriginous Eczema, and Lichenification.**—Sir Malcolm Morris regards as pruigo an itching affection which presents an eruption of discrete hard papules followed sooner or later by the peculiar roughening and thickening of the skin known as lichenification. The disease usually begins in early infancy, between the eighth and the twelfth months of life. The papules are hard, small, often perceptible only to the touch, pale or reddish in color, and distributed principally on the extensor surfaces of the limbs, the lower part of the abdomen, the sacral region and buttocks, and the back and front of the chest, but sparing the joint flexures. They give rise to violent itching and, when subjected to the irritation of scratching, become reddened and increase in size. When a papule is excoriated serum and blood exude, which quickly dry into a brown crust. Other lesions appear which may resemble those of eczema (except that the flexor surfaces are still usually spared) and of urticaria, and finally the skin becomes lichenified. One crop of papules succeeds another, and the disease becomes chronic, but usually there is some abatement in summer, with exacerbation in winter. In severe cases the integument takes on a brown color, there is desquamation, the hairs are extruded, there are pustules and sores, and the femoral and axillary glands enlarge and may go on to suppuration. One peculiarity of the disease is that after the third year of life it undergoes no further evolution. The exciting cause of prurigo has been found in bad hygiene, defective alimentation, autointoxication, etc. Brocq finds the true cause in hereditary cross-breeding in which four influences cooperate, namely, (1) the neurotic condition of one or both parents, either of long standing or operating during the mother's pregnancy; (2) lymphatism, either idiopathic or due to tuberculosis or syphilis; (3) autointoxications originating in arthritism and aggravated by bad hygiene and by life in crowded cities; (4) chronic intoxications, in which alcoholism and caféism take the principal rôle. The complicating lesions having been dealt with, the indications for treatment, as Colcott Fox says, are to improve the patient's nutrition by good hygiene, generous diet, and cod liver oil; to control the itching by baths medicated with starch, sulphurated potash, creolin, etc., and to dissipate any coexistent eruption. All irritating preparations must be avoided. The external remedies employed by the Vienna school are sulphur, tar, soap, and naphthol. The tar is used especially to control the itching. Brocq holds that the best of the topical remedies is cod liver oil, one recommendation of which is that it can be used in all stages of the affection, even the most acute. If the surface is smeared with the oil the applications must follow each other quickly; and he considers it better to

envelop the parts in an impregnated many-folded bandage covered with an impermeable varnish. He speaks highly of a preparation of cod liver oil and white wax in the proportion of three to one, used as a pomade, with or without covering. There is no pruriginous affection in which the itching is more intense than in pruriginous eczema. The word "lichenification" was applied by Brocq to the peculiar roughening and thickening of the skin, which so frequently followed scratching. Untreated, the patches may persist for many months or for years, or the itching and scratching ceasing, they may gradually disappear. The lichenification itself may be treated either with the *x*-rays or with radium. The author has had the best results with the latter.

2. Fevers of Obscure Origin in Infancy.—C. P. Lapage states that when confronted with a case of fever in a child—fever which has no obvious cause on clinical examination, and which is not merely temporary, passing off with a purgative—it is best to proceed by a process of exclusion. One must examine carefully first for chest conditions, such as deep-seated or apical pneumonia, localized empyemata, collections of pus; then for tonsillar, pharyngeal, or nasopharyngeal conditions, and for otitis media (this last a by no means uncommon cause of fever, and one needing some skill to diagnose); and, finally, for abdominal conditions, such as appendicitis. Post-influenzal conditions may give rise to much anxiety, because there may be so little to show for the temperature, and visions of many far more serious conditions pass across the mind of the medical attendant, who can only have recourse to the process of elimination. Another common but obscure cause of fever is the presence of caseous glands, either bronchial, mediastinal, or mesenteric. In some cases they are so marked as to be obvious on palpation or percussion, but in most cases they are by no means easily diagnosed, the only symptoms being of a general nature. The cutaneous tuberculin reaction and the history are both valuable, while careful palpation of the abdomen is needed, and examination by the *x*-rays is a very important asset to one's means of making a diagnosis. Rheumatism is perhaps one of the most important of the causes of fever in children, and, what is more, its ravages may be of an obscure nature. Leucemia and Hodgkin's disease may run a high course with exacerations during which there may be high fever. An obscure but common cause of fever is infection of the urinary tract with *Bacillus coli communis*. Inanition fever must be borne in mind. A state of chronic intestinal indigestion is very common in young children, and such cases often have slight but definite rises of temperature of an irregular nature. Typical cases show wasting, a large abdomen, general flabbiness, and other symptoms pointing to a chronic toxemia. The stools are characteristic, being frequent, of large amount, and very offensive; they usually contain particles of incompletely digested food. Postbasic meningitis in infants may sometimes cause fever without definite signs to guide one to the correct diagnosis. Meningitis is often difficult to distinguish from pneumonia, either apical or deep-seated, and from typhoid fever.

3. Study of an Epidemic of Measles.—A. E. Tait presents the results of a study of an epidemic of measles involving 437 cases. He notes that in the first five years of life the fact is remarkable that the curves of pulmonary complications and death percentages are parallel. The cases of measles were most numerous in the fourth year of life, with 16 per cent. pulmonary complications, and no deaths. The total death rate of the epidemic was 5.03 per cent. Severe pulmonary complications supervened in 23.57 per cent. of all cases. Pneumococcal infection was the cause of the mortality. Empyema was conspicuous by its absence. Middle ear disease was common, but was amenable to fomentations, mild lotions, and hexamethylenetetramine internally. Diarrhea occurred in 10 per cent. of the cases during the invasion, with the rash, or afterwards, and sometimes during incubation. Alarming croupy symptoms with the rash sometimes occurred, but quickly subsided. Most dangerous were those cases with mild coryzal symptoms and rash, apparently a mild attack in which on the second or third day of the rash acute dyspnea suddenly appeared, a rise in temperature, uncountable pulse, and great restlessness, often ending in death in twenty-four to forty-eight hours. This complication was attributed to collapse of lung.

4. Aneurysm of the Superior Mesenteric Artery with Rupture.—A. H. Gifford reports a case of this condition, the interesting points of which were as follows: (1) The aneurysm must have been one occurring in the superior mesenteric artery in its course behind the pancreas, remnants of the arterial wall being found lying flat on the posterior wall of the cavity. (2) The gradual dilatation of the large aneurysmal cavity had exercised a traction on the aorta itself, so that a fusiform aneurysm was formed. (3) There was a rotation of the aorta, in that the opening of the celiac axis and what must have been the opening of the superior mesenteric artery originally, were found on the right side of the aortic aneurysm. (4) There must have been a gradual and persistent dissection in the upward direction to the lower surface of the liver where the rupture eventually took place, as was evidenced by the thickening and induration of the walls.

2. The Etiology of Torsion of the Testis. R. W. Murray.
3. Acute Epididymitis Produced by Muscular Strain. J. W. G. Grant, F.R.C.S.
4. Notes on Sleeping Sickness: Suggestions as Regards Gland Puncture and the Trapping of Tsetse Flies. A. Balfour.
5. The Necessity for the Use of Color Names in a Test for Color-Blindness. F. W. Edridge-Green.

1. Puerperal Infection.—J. Furneaux Jordan differentiates three types of case: 1. Those that are of a mild type and recover easily. 2. Those that are acutely infected and die quickly. 3. Those that are severely infected or ill for a long time, and usually, but not always, recover. If the first rise of temperature is in the first 48 hours and is only a slight one, when there is not great rise in the pulse rate, and the patient does not feel very ill, the best procedure is to wash out the uterus. In many cases the temperature will fall the next morning and never rise again. If the temperature is high, or persists or recurs, the steps to be pursued are as follows: A culture should be taken from the interior of the uterus, and an autogenous vaccine should be prepared. The uterus should be freed of any retained placenta or membranes either manually or by means of a blunt curette. The uterus should then be swabbed out with a piece of cotton dipped in a dilute solution of mercury biniodide, and a drain of iodoform gauze should be inserted. Following this it is considered advisable to give the patient an injection of vaccine containing 25 or 30 million of the *Streptococcus puerperalis*.

2. Etiology of Torsion of the Testis.—R. W. Murray states that in the majority of reported cases the testicle had not descended to the scrotum. The majority of cases occurred in young persons about the age of puberty. In nearly one-half of the recorded cases no definite reason could be given for the torsion occurring. Not infrequently the symptoms occurred while the patient was in bed, and in some cases during sleep. In many instances of acute torsion there had been slight recurrent attacks of pain. In every case operated upon the testicle was found to be twisted upon the epididymis, or both testicle and epididymis were twisted upon the cord. In every case in which the testicle has been untwisted and replaced atrophy of the organ has resulted.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

Thyroid Gland.—It is advisable to make a special search for the presence of goiter, as a small one is very apt to be missed. A study of this subject shows that while these cases are not entitled to ordinary forms of policies, some of them are acceptable for endowment or rated-up policies, and the examiner is, therefore, depended upon to furnish the following data:

1. How long has the growth existed?
2. Has it increased in size during the past five years?
3. Is it substernal?
4. Is the goitre due to simple hypertrophy or hyperplasia, or is it cystic or degenerating?
5. Is it accompanied by symptoms due to pressure or to any effect on the nervous system?
6. Is there any exophthalmos?
7. Does the applicant live in a healthy environment free from scrofula and tuberculosis?

Abdominal Organs.—The physical exploration of the abdominal organs does not always yield the satisfactory results in diagnosis obtained from the examination of the contents of the thorax. Nevertheless, it is imperatively necessary to regularly look for indications of certain pathological conditions. The examiner is urged to follow the suggestions offered in the following sections in order to avoid the correspondence which the home office will surely call for in all cases if the particulars, where there is a history of abdominal pain or colic or indigestion, do not appear in the original report.

Liver.—The liver should always be mapped out so that its size and location may be definitely determined, especially when alcoholic habits are suspected. Moreover, the examiner should never fail to inspect the right hypochondriac and pyloric regions for the presence or after effects of gall stones, most particularly so when there is a history of abdominal pain or colic, indigestion or jaundice. Tenderness as well as tumefaction should be reported in every case when it is found.

Spleen.—The mapping out of this organ is difficult unless it is enlarged. An effort should be made, however, to make out the size when there is a history of malaria, recent typhoid or some disorder of the blood.

Appendix.—Deep pressure for the detection of tenderness or a tumor should be made over the site of the appendix in every case where there is a history of indigestion, bilious attacks, nausea, abdominal pains or colic. In recent cases of any of these disorders the home office officials will usually require a statement from the attending physician, furnished by the applicant, who has the advantage of having observed the condition at the time of its occurrence and is therefore in a better position to state if there was any suspicion of gall stones or appendicitis. The examiner will save valuable time by anticipating this request at the time of the examination. When there has been an appendectomy the home office officials will want to know if there is any undue sensitiveness or induration of the scar and whether or not there are signs of a hernia.

Hernia.—The abdominal, inguinal, and femoral regions should be looked over for the possible presence of a hernia. Whenever a hernia is found it is most important for the examiner to ascertain if it is easily reducible and if the bowel is being well maintained in its normal position by a properly fitted truss. The usefulness of the truss should be determined, for a very large number of those worn are not only absolutely useless, but even harmful. When the hernia is easily reducible but no truss is worn, the examiner should explain the importance of a proper apparatus to the applicant and persuade him to procure and wear one, for most insurance companies insist on this before issuing a policy.

Life Insurance Examinations.—It was recently said by the physician in chief of a large life insurance company that upon investigation it was found that with all their examiners only 25 per cent. of the applicants were completely examined. In other words, histories were poorly and inaccurately taken, the heart and chest were frequently examined without the patient removing his clothing and special examinations of blood pressure, uranalysis, etc., were very carelessly made. This criticism not only reacts upon the individual doctor, but makes an extremely poor impression upon many business men connected with insurance companies and upon the applicant examined. To be appointed examiner for a life insurance company is not only an honor and a responsibility, but it is a legitimate means of gaining skillful experience and increasing practice. The man without a physician often takes for his family doctor some physician who has examined him for life insurance. Insurance companies are now making rigid investigations of their examiners and it behooves every practitioner who does insurance work to do the work for which he is well paid thoroughly, accurately and conscientiously.—*Old Dominion Journal of Medicine and Surgery*, April, 1912.

Associations of Medical Examiners.—From time to time associations of medical examiners have been organized in different parts of the United States and generally with local patronage only. Some of these have been in cities, such as the Boston Society of Examining Physicians and Surgeons, the Chicago Medical Examiners' Association, and the Louisville Medical Examiners' Association. Others have been organized in a certain portion or section of the country, such as the Massachusetts Society of Examining Physicians, the Pacific Coast Association of Insurance Examiners, the Kentucky Association of Medical Examiners, and the Inter-State Examiners' Association. Knowing the fate of local and sectional medical examiners' associations during the fall of 1900, several medical examiners met with Dr. Thos. J. McGowen in Vincennes, Ind., and organized the American Association of Medical Examiners, electing Dr. McGowen president thereof. During the year 1911 the Inter-State Association of Medical Examiners was taken in as the Northwest Section of the American Association of Medical Examiners. In Europe there are medical examiners' associations, usually one to each large country. The Life Assurance Medical Officers' Association, one of the largest, meets quarterly in London. Dr. Frank W. Foxworthy is of the opinion that if all the examiners' associations in this country were merged into one large body more could be accomplished.—*Proceedings of the Second Mid-Year Meeting of the Medical Section of the American Life Convention.*

Book Reviews.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc., etc. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. A. . . . Volume I, Twenty-second Series, 1912. Price $2.00. Philadelphia and London: J. B. Lippincott Company, 1912.

The present volume of this well-known quarterly publication consists of twenty-one articles on diagnosis and treatment, medicine, surgery, diseases of the ear, etc. Among them may be named Wollbarst's study of the source of pus and shreds in the urine. Taylor's article on venereal disease in the United States Navy, Simon Flexner's paper on experimental poliomyelitis, etc. The papers keep up the usual high standard of this periodical.

What to do in Cases of Poisoning. By William Murrell, M.D., F.R.C.P., Senior Physician to the Westminster Hospital; Lecturer on Clinical Medicine and Joint Lecturer on the Principles and Practice of Medicine; Late Examiner in the Universities of Edinburgh, Glasgow and Aberdeen and to the Royal College of Physicians of London. Eleventh edition. Price, $1.00. New York: Paul B. Hoeber, 1912.

This admirable pocket manual is so well known as to require no introduction. It discusses in a most comprehensive manner not only the common acute and chronic forms of poisoning, but also the unusual forms, such as poisoning by hair dyes, novocaine, and veratria, bee stings, vitriol throwing, etc. One cannot conceive of a more useful volume that the practitioner should have within easy reach for quick reference. It is small and compact, and may be conveniently stored away in the emergency packet.

Thérapeutique Usuelle du Praticien, Traité de la Tuberculose. Par Albert Robin, Professeur de Clinique Thérapeutique à la Faculté de Médecine de Paris; Membre de l'Académie de Médecine. Troisième Série. Price, 8 francs. Paris: Vigot Frères, 1912.

The third volume of this monumental work on therapeutics is devoted exclusively to the treatment of pulmonary tuberculosis. The eminence of the author both as a clinician and as a teacher is such that the reader and student are already prepared to find this volume one in which thoroughness of presentation and practical utility go hand in hand. The work is divided into six parts. Part I deals with the treatment of pulmonary tuberculosis under the following chapter headings: general consideration on tuberculosis and on its soil; the acceleration of the respiratory exchanges; organic demineralization; and indications for treatment of the tuberculous predisposition and of confirmed phthisis. Part II deals with hygiene and alimentation. Part III takes up the subjects of restricted medication, the principles of remineralization and their application, the remineralization medication, direct and indirect antiseptic treatment, local medication and revulsion, tuberculin therapy, antitoxins, the practical association of the five fundamental forms of medication, the treatment of acute phthisis, the treatment of symptoms, accidents, and complications, hydrotherapy, hydromineral cures, and climatotherapy. Part IV discusses the treatment of tuberculosis according to the age of the patient and the associated morbid conditions. Part V deals with the extrapulmonary localizations of tuberculosis. Part VI discusses the social defences against tuberculosis. This summary shows that the author is not a disciple of therapeutic nihilism. A great deal can be done to arrest the progress of tuberculosis and to relieve its symptoms. The reviewer is aware of no work in which the therapeutic resources for combating tuberculosis are presented in greater detail or with greater thoroughness than in this volume.

Theorie und Praxis der Inneren Medizin. Ein Lehrbuch für Studierende und Ærzte. Von Erich Kindborg in Bonn. Zweiter Band. Die Stoffwechselstörungen. Die Krankheiten des Bewegungsappartes und der Verdanungsorgane. Mit 74 Abbildungen. Price, 10 marks. Berlin: Verlag von S. Karger, 1912.

The plan of this work, which was set forth in the review of the first volume, is to present the subject of internal medicine with full reference to the auxiliary sciences of physics, chemistry, and physiology. The present volume discusses the diseases of metabolism, the diseases of the locomotory apparatus, and the diseases of the digestive apparatus. By reviewing the mains facts in the elementary sciences upon which the theory and practice of medicine depend, the author assists the student in gathering together the scattered threads of knowledge in forming the larger concepts of disease and its management. Thus, in discussing the diseases of metabolism, the author introduces the subject with a brief exposition of caloric values and the various stages in the physiology of metabolism. In connection with the diagnosis of diabetes the physics of the polarization of light is fully presented with the aid of illustrative diagrams. The chemistry of digestion and the various chemical methods employed in the clinical diagnosis of gastrointestinal diseases are all fully presented in connection with the discussion of these diseases. In this effort to coordinate the practice of medicine with the elementary sciences, the author follows a sound pedagogical rule. At the same time the practical needs of the student are not overlooked. Treatment is accorded considerable attention. The work is strictly up to date, as may be noted in the description of radium and its application in the treatment of gout.

Der Infantilismus, die Asthenie und deren Beziehungen Zum Nervensystem. Von Prof. Dr. Paul Mathes, Privatdozenten für geburtshülfe und gynäkologie an der Universität in Graz. Mit 8 Abbeldungen in Text. Price, 6 marks. Berlin: Verlag von S. Karger, 1912.

In this monograph there is presented a learned exposition of the subject of infantilism from the viewpoint of the gynecologist. The work is divided into two parts. Part I deals with the anatomical characteristics under the following headings: infantilism proper, and asthenic enteroptosis. Infantilism proper includes infantilism of the skeleton, genitals, vascular system, the thymicolymphatic variety of Paltauf, and the forms of local infantilism. In the section on asthenic enteroptosis, which, according to modern German writers, represents a form of physiological infantilism, the author discusses the mechanics of the bodily cavities during rest, during respiration, and in enteroptosis; the mechanics of the pelvis, prolapse, visceral weaknesses, and the period of incidence and frequency of the asthenic enteroptosis. Part II deals with the clinical phases of infantilism, its psychic and sympathetic accompaniments, and its manifestations in the circulatory and respiratory apparatus and the digestive organs, including the biliary passages and the appendix. The sexual organs present many phenomena that are included in the category of infantilism: the disturbances of menstruation; the psychic disturbances accompanying the menarche or the establishment of the menstrual function; the disorders of puberty and of the climacteric, and the diseases of the sexual organs. The prognosis and course of these conditions, their therapy, and the social relationship of the victims of infantilism and of the asthenic habitus form the concluding topics in this most comprehensive volume. The importance of the modern conception of infantilism in its numerous ramifications in clinical medicine, pediatrics, gynecology, and neurology, should make this work one of peculiar interest and value to a large circle of medical readers.

Der Gynäkologische Operationskursus. In sixteen lectures. By Dr. Wilhelm Liepmann, Berlin. With 409 illustrations. Second Edition. Berlin: August Hirschwald, 1912.

The second edition of this interesting book has appeared so soon after the first that necessarily it can record but little actual progress. The author has thoroughly revised the old text, however, and added twenty-two new illustrations. He has also expanded the description of the transverse incision between the pubic tubercles and of the combination of the Alexander-Adams operation with laparotomy. Liepmann also proposes a new ligament, the infundibulocolic, which he considers of interest to both the clinician and the operator. The numerous illustrations are of such an excellent character and form, such an important feature in the work that a personal inspection is necessary to appreciate them. In the description of cesarean section, which with certain other obstetrical operations, seems somewhat out of place in a gynecological manual, no mention is made of the high median abdominal incision, which has been quite largely developed in this country, or of the incision low down in the posterior segment as advocated for septic cases. The use of the elastic bag in doing a vaginal cesarean section seems also unnecessary in the majority of the cases. The author's descriptions throughout the book might be improved upon if they were somewhat less disjointed. Otherwise, the book is worthy of praise for the novelty shown in the presentation of the subject. It affords an excellent review of modern German operative procedures in gynecology and is worthy of attention by American operators.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Annual Meeting, Held at Hot Springs, Va., May 29, 30, and 31, 1912.

The President, Dr. Walter Lester Carr of New York, in the Chair.

(*Concluded from page 88.*)

Thursday, May 30—Second Day.

Some Fundamental Principles in Studying Infant Metabolism.—Dr. Fritz B. Talbot and Dr. Francis G. Benedict of Boston presented this communication. They stated that knowledge of the energy requirements of infants and the energy content of their food was of fundamental importance in studying their rate of growth and in the treatment of nutritional disorders. The ideal method of determining the energy transformation of infants was that of direct measurement of the heat eliminated and produced, but this involved expensive, elaborate apparatus. The method which they used was that of so-called indirect calorimetry, *e.g.* a computation of the energy transformations from the gaseous exchange. It was pssible to compute with considerable accuracy the energy transformations of an infant from the amount of oxygen consumed and the amount of carbon dioxide produced. The direct measurement of oxygen in young infants had but rarely been determined. Direct determination of carbon dioxide was less difficult and had frequently been made in foreign laboratories. It was the purpose of the paper to point out the inconsistencies arising from the determination of carbon dioxide in infants without taking muscular activity into consideration. They were disposed to question the desirability of long experimental periods for establishing the basal metabolism of infants when such periods might include not only quiet sleep but also periods of activity and even crying. It was necessary to find out what was the ideal length of the experimental period in the infant. This, they thought, was the period when the baby was asleep, absolutely quiet muscularly, and preferably without food in the stomach. The apparatus they used was a modification of that of Benedict and Hamans for experiments upon hypophysectomized dogs. All metabolism experiments in infants made without controlled pulse rates and without graphic records of muscular activity were lessened enormously in value by these two factors.

Dr. John Howland of St. Louis said that if they were able to further perfect the apparatus so that the amount of oxygen could be determined as well as carbon dioxide they would have added enormously to their facilities. Instruments such as Dr. Lusk had used were too expensive and it required four trained men to manage one of them. The methods employed in this country and abroad differed widely. Abroad they were using apparatuses of fifteen or twenty years ago and the results were of no use to investigators in this country. Their results were full of mistakes. Their time periods were twenty out of twenty-four hours, taking children awake, asleep, or crying. These children could not be kept quiet and the result was that the first period of metabolism was 20 or 25 per cent. higher than it was during the last period when the child became accustomed to the apparatus. Dr. Howland hoped that a formula would be found which would not require the estimation of square and cube roots and which could be used more readily and more accurately.

Dr. Fritz B. Talbot of Boston, in closing the discussion, said that with regard to the relation between the pulse rate and muscular activity about which Dr. Hamill had asked, he did not know whether there was a definite relation. When the baby was quiet apparently the pulse was at its minimum rate. The charts showed that the pulse varied from ten to fifteen beats during the course of three or four minutes. During the greatest muscular activity the pulse went to its highest point. He did not have sufficient data to enable him to draw definite conclusions as to how much the elevation of the pulse would modify the amount of carbon dioxide excreted. Apparently there was a definite relationship. If the charts were sufficiently studied it would be noted that, in certain instances, there was not sufficient exercise recorded to correspond to the elevation of the pulse rate. His only explanation for this was that the pulse rate was only taken once in every six minutes and the baby might have moved two minutes before. He hoped that by fall they would so perfect their apparatus that it would be possible to estimate the amount of oxygen.

A Case of Retarded Development in a Boy Treated with Thymus Extract.—Dr. Charles Gilmore Kerley and Dr. S. P. Beebe of New York reported this case. The patient, a boy, 16 years of age, was delicate in appearance and normal mentally. The penis was small and shrunken, the testicles very small; and although they could be brought into the scrotum, they rested in the canal the greater part of the time. There had never been any erection of the penis. Tonic and hygienic treatment was instituted and at the end of nine months there had been a gain in weight of three pounds, but there was no change whatever in the genitals. Desiccated thymus extract was then given, 15 grains daily. During the first six months of this treatment the genitals, penis, and testicles enlarged, and after nine months' use the first erection occurred. At the end of one year's treatment hair began to appear on the pubis and in the axilla and the patient had gained in weight as well as in height. The testicles had remained in the scrotum during the past six months. The sexual organs were now apparently normal.

Dr. L. Emmett Holt of New York said that the paper was interesting, but, so far as his experience went, not conclusive. He had seen boys develop so slowly that the advance was imperceptible, then all at once take a start and improve wonderfully without any medication. One should be very careful in drawing conclusions in regard to these so-called specific medications.

Dr. John Ruhräh of Baltimore said that in many cases of advanced marasmus he had used the thymus and the results were about the same whether this agent was used or not. He felt that there was some close relation between the thymus gland and growth and that if it were possible to give enough one might obtain very satisfactory results. Williams had obtained some striking results with thymus extract in cases of malnutrition and he had tried to find out what cases were benefited by this treatment, but it seemed to him only a case of "hit and miss." It made no difference whether they used thymus or thyroid, the results were the same.

Dr. John Howland of St. Louis said it was next to impossible to get evidence of any kind regarding the thymus. A report appeared some years ago on the results of removal of the thymus in dogs; after removal of the gland the bones of the dogs were fractured and it was found that union was delayed and but little callus formed. When these results were published they were questioned by a good observer. In New York City they had removed the thymus from young puppies and from premature animals delivered by cesarean section, with no results whatever. The experiments were changed to other animals, but it could not be determined whether the removal of the thymus made any difference in the growth of the animal or not. So far as children were concerned the removal of the gland did not seem to be followed by any bad effects; but such cases should be followed at least to the time of puberty. Any medication like this was like "hitting in the dark," for other glands might have been used with similar results.

Dr. Frank S. Churchill of Chicago said he could not agree with Dr. Howland. There were a number of cases on record where the thymus gland had been removed, almost enough to draw conclusions. It was impossible to entirely remove the gland in infants; after the completion of the operation there would be enough left behind to perform whatever function was necessary.

Dr. J. P. Crozer Griffith of Philadelphia said that the work of a Belgian physician along these lines had interested him and he now had three cases under observation. The Belgian physician had reported one case in which the pituitary gland extract was supposed to have produced excellent results; he was now using that agent in one case, but thus far could see no results. So far as gain in weight was concerned, he did not know which, if any, of these internal secretions to give, or if any of them could be trusted to do good. When they were studying the growth of children they might look in other directions and think of what the neurologists had taught them regarding the rest cure treatment. No child knew how to care for himself, and the parents did not know how to care for the child and usually pushed him mentally and physically. For a number of years, when treating any child who was not doing well, he had enforced rest upon him and had reached the conclusion that the results were extremely valuable.

Dr. Henry Heiman of New York said that the use of these organic products was empirical, but that the administration of thyroid in one grain doses three times a day had given excellent results. He had used it in cases which, like Dr. Kerley's, were in fact cases of infantilism.

Dr. Charles Gilmore Kerley of New York, in closing

the discussion, said that so long as he could keep this boy growing he would continue the use of the thymus extract. What he had given them was simply an exhibit; he did not draw any conclusions. He had two other boys under treatment and they had grown in height, as they had not done before the administration of the thymus.

The Dextrins and Maltose in Infant Feeding.—Dr. Thomas S. Southworth of New York read this paper. He said that in health infants seemed to take with about equal facility the three sugars most commonly employed in making up the deficiency of carbohydrates in diluted cow's milk, namely, milk sugar, cane sugar, and so-called malt sugar, but it had remained for recent investigators of the pathology of nutrition to assign to each of these forms of sugar its relative position as a disturbing factor. Although the advantages of the so-called malt sugar, or maltose, had again received wide recognition for purposes of restoring deficient or halting nutrition in infants, and for furnishing sufficient calories during recovery from food injuries there had been little appreciation of the *rationale* of its action. The terms malt sugar and maltose were inaccurate and misleading. While pure maltose was a rare product of the laboratory, too expensive for general use, and consequently never employed for infant feeding, the commercial products to which this generic term was too often loosely applied were numerous and it was doubtful whether any two of them had the same composition. The term embraced almost any preparation produced by the action of diastatic ferments upon starch. While lactose and saccharose were given in the food by themselves maltose was never administered without an admixture of dextrins, which latter, while capable of being further elaborated into maltose, and subsequently into dextrose, had, for the time being, very different chemical and physical properties. This association of the dextrins with maltose, instead of being a negligible matter, was a factor of considerable importance and might be assumed to play a large part in the favorable effects of the malt preparations in disturbed conditions. Although malt preparations were spoken of as less fermentable than other sugars, it was, of course, an error to think of maltose itself as not liable to fermentation of certain types, since this property of maltose was relied upon in all brewing operations. Dextrin remained unfermented in beer and was immune to fermentation in the intestine until reduced to assimilable maltose. The presence of dextrin played no small part in the therapeutic and nutritive values of maltose dextrin preparations. An interesting field of research was now open for determining the nutritive and therapeutic values in normal and pathological cases of high, average, or low percentage of dextrin in maltose-dextrin mixtures.

Maltose in Infant Feeding.—Dr. John Lovett Morse of Boston said there were three different sugars used in infant feeding, lactose, saccharose, and maltose. Maltose was seldom, if ever, used in pure form. These sugars were all disaccharides, lactose being a combination of dextrose and galactose, saccharose of dextrose and levulose. The dextrins were bodies formed in the change from starch to maltose, and there was a great variety of them. Their composition was not well known. The disaccharides were not absorbed as such from the intestine under normal conditions, but were first broken down into their respective monosaccharides by special ferments, maltase, saccharase, and lactase. These were found in the mucous membrane of the small intestine. Maltose was the most quickly absorbed of the three disaccharides and saccharose next. The disaccharides were all fermentable. The composition and maintenance of the normal fecal flora was without question due to the relative excess of carbohydrate, in the form of lactose, in the milk. It was, therefore, of importance to have a considerable amount of sugar in the food of babies fed on mixtures of cow's milk. According to Kendall lactose favored the growth of the *Bacillus bifidus*, while maltose favored the growth of the *Bacillus acidophilus*, which, though normally present in small numbers, if present in large numbers was liable to produce an excessive degree of acidity which might cause intestinal irritation and intolerance for sugar. Finkelstein and Meyer recommended the use of malt sugar in connection with their "eiweiss-milch" after the disappearance of acute symptoms in order to avoid loss of weight and disturbance of nutrition. The use of this method of treatment during the past year had convinced him that there was a variety of intestinal indigestion in infancy which was relieved by reducing the sugar and salts in the food to the minimum and giving large amounts of casein and that the dextrin-maltose preparations could be given to these patients sooner than lactose without causing a return of symptoms. This type was characterized by a number of stools of diminished consistency, green in color, often frothy, acid in reaction, and not infrequently containing mucus and fat curds. In feeding normal infants lactose was for many reasons preferable to maltose, but there was a type of indigestion due to fermentation of sugar in the treatment of the convalescent stage of which maltose was better borne than lactose. Maltose was contraindicated in the treatment of diarrhea due to the gas bacillus and similar organisms and was less useful than lactose in the treatment of those diarrheas caused by the dysentery bacillus.

Dr. John Howland of St. Louis said more work should be done in the investigation of the dextrins. They had been told that feeding infants with pure dextrin and no maltose was not good; they had also been told that ten babies thus fed by Keller had died as the result, and, therefore, they had not used pure dextrin. The Germans looked upon the use of lactose in normal children as dangerous and cited their experiments on puppies. However, the puppies that had rickets did well on this feeding; if they were fed on glucose and maltose they did badly; if they were fed upon saccharose they died. Dr. Howland did not think the use of lactose was dangerous in dysentery; in large quantities it would increase the diarrhea and this should be borne in mind. The experimental reports showing lactose to be a useful form of treatment must be accepted.

Dr. Isaac Abt of Chicago said that he had been using the malt preparations for some time and normal children did very well so far as the gain in weight was concerned. It was well known that all the preparations belonging to the malt-dextrin group would cause constipation, and, therefore, it was necessary to add some substance to overcome this tendency. When combined with lactose there was less tendency to constipation. The whole subject of the bacteriology of the gastrointestinal tract remained in such an indefinite state that one could not as yet draw any conclusions from the work that had been done, much less could sugars be prescribed on the basis of the intestinal flora. Too much importance was being given to the sugars alone. It seemed to him that the normal child did equally well on malt sugar, cane sugar, or sugar of milk.

Dr. Rowland G. Freeman of New York said he thought the warning as to the use of malt sugar was timely. All babies should have a chance at normal feeding before being given the abnormal. There was a tendency to place children on these malt foods because they grew faster. Investigation had shown that in many cases scurvy was due to the use of proprietary foods; those that he had seen himself were fed on malt foods. If the babies did not do well on lactose, then one should change to maltose.

Dr. L. Emmett Holt of New York said that it was a fact that children fed on maltose did develop scurvy. The use of lactose would overcome the constipation from which so many children suffered and, in his opinion, the liquid preparation was better than the dried ones. In a study of certain sugars made last year it was found that lactose in solution was practically sterile as was cane sugar, but maltose preparations contained many organisms that were quite pathogenic. These organisms were killed only by a high temperature (the boiling point for twenty minutes). That temperature would change the composition of the sugar. They still had much to learn about variations in sugars and their use in abnormal cases. The use of cane sugar in diarrhea, where both malt sugar and maltose were badly tolerated, was a great advantage. That was the secret of success in the use of ordinary condensed milk. Dr. Holt said that in the main he agreed with the conclusions drawn.

Dr. L. E. LaFetra of New York said that he had decided that the use of milk sugar did harm especially in certain cases. Cases of diarrhea occurring in some hospital patients would improve when cane sugar, or one of the dextrin malt preparations was used, or when the amount of milk was lessened. During the past ten months he had been using not only cane sugar, but the malt preparations as well and had obtained the best results. In many cases of diarrhea they obtained the best results by diminishing the amount of sugar of milk. In cases with thin acid stools and large amounts of mucus and blood it was a mistake to resume the use of sugar of milk too early.

Dr. Henry L. Coit of Newark, N. J., said he believed that there was a chemical as well as a gross difference due to contamination between mother's sugar of milk and the commercial sugar of milk, and for that reason he had tried to get at the firms that were marketing the sugar of milk. After considerable difficulty, he had obtained an audience with the chemist of one firm who admitted the presence of bacterial toxins, but said that the sugar of milk answered the requirements of the

pharmacopœia. Professor Leeds had made an investigation and had found that sugar of milk was full of bacteria and also of chemical impurities. One should never use more than one ounce of sugar of milk and this should be boiled. The brand of milk sugar known as "XXX" was the finest and was prepared by redissolving the ordinary product, filtering it, and boiling it down until it formed into crystals.

Dr. J. P. Crozer Griffith of Philadelphia said he wished to call attention to the fact that a committee had been appointed to study scurvy and had reported that a large number of cases of that disease were caused by malt preparations.

Dr. Alfred Hand, Jr., of Philadelphia said that while he had never conducted a scientific investigation on the influence of sugars in infant feeding, he had the impression that lactose tended to produce diarrhea. In private practice where milk sugar was used so much there was a tendency to constipation. Where a child was obstinately constipated, lactose or saccharose had a tendency to regulate the bowels.

Dr. Thomas S. Southworth of New York said that Dr. Morse had spoken of the disadvantages of the use of starch, and he, himself, had long maintained that starch could be overused in children and one should be careful as to the amount used, especially of the various diluents. He had used barley water widely during the past decade in children who were not doing particularly well on other diluents. Dr. Southworth said that he had been interested in Dr. Abt's statement regarding the use of malt-dextrin mixtures being constipating rather than laxative; this corresponded with his own experience. This effect was probably due to the extraction of fluids from the tissues.

Dr. John Lovett Morse of Boston said that he could not see a single reason for the use of milk sugar. There were those who claimed that the milk sugar of cow's milk was chemically different from the milk sugar of mother's milk. This was not true; chemically they were the same. Boiling the milk sugar might destroy the bacteria but it did not destroy the toxic products. Dr. Morse referred to Dr. Kendall's work in Boston and said that during the summer of 1910 they had given the babies with diarrhea a solution of maltose and all the men on the hospital staff felt that only good had resulted.

Friday, May 31—Fourth Day.

Serum Treatment of Pneumonia.—Dr. Rowland G. Freeman of New York read this paper. He said that of the three treatments that were based on laboratory investigation one might mention the use of leucocyte extracts advocated by Hiss, the use of vaccines either commercial or autogenous, and the use of the serum. He had tried the antipneumococcus serum on account of the usually favorable results reported. The cases admitted to the series were those with high temperature with good signs in the chest. He used alternate cases as controls. In none of the cases was there any irritation at the point of injection. In all of the cases the injections were followed by urticaria, but without fever or general disturbance. The average age of the children injected was twenty months, and of the controls 11 months. In many cases there was an immediate change in the appearance of the child. Children that looked septic in several cases after the injection had a good color, were brighter, took feeding better, and seemed much improved, although the condition in the lung was no better or spreading. The serum injections, while apparently affecting the course of the disease favorably in some instances, appeared to have no result in others; in most cases there appeared to be a better reaction on the part of the child after the injection than before. The injection was usually followed by some reduction in leucocytosis and the percentage of polynuclear leucocytes increased. In these favorably influenced cases there was little spreading of the disease after injection, and in some a fairly rapid resolution. The pneumococcus serum presented a safe method of attempting to influence the course of pneumonia in children; the addition of antistreptococcus serum seemed to offer no advantage over the use of the pneumoccocus serum alone.

Dr. Matthias Nicoll, Jr., of New York said that he had had a fairly large experience with the pneumococcus serum both in children and in adults and he thought that Dr. Freeman's conclusions were those that all must arrive at, namely, that the case was not proven. Sometimes good results were obtained and at others no results at all. One should give large doses, at least 100 c.c. Dr. Nicoll related his experience in attempting to immunize diphtheria patients against pneumonia and could not see that the mortality rate was affected by the use of the serum. It was difficult, therefore, to have a great deal of faith in the curative value of a serum which had so little apparent protective power against the organism whose activities it was designed to control. Dr. Nicoll said he preferred to give the serum intravenously, but that a dose of 100 c.c. could easily be given subcutaneously. The serum should be given in prolonged cases of pneumonia where the patients seemed to be daily losing ground. He had never seen any bad results from the injections even when large doses were given intravenously.

The Employment of Salvarsan in Infants and Young Children.—Dr. L. E. LaFetra of New York read this paper. If they considered only the moderate grades of congenital syphilis the older methods had been quite satisfactory. On account of the high mortality of the serious cases and the possibility of late manifestations of the disease a more powerful and certain remedy was needed. Salvarsan might be given indirectly to the infant by injecting the mother during gestation or lactation, or it might be given directly to the infant. The subcutaneous method produced bad sloughs or cellulitis and had to be abandoned. Since June 11, 1911, in the Children's Wards of Bellevue Hospital, Dr. LaFetra had treated 25 cases of congenital syphilis. Of these 10 received salvarsan either with or without mercurial treatment, while 15 were treated by mercurials alone. The ages of the 15 patients in whom only mercury was used ranged from three weeks to one year, most of the babies being about three months of age. The ages of the 10 cases treated with salvarsan ranged from two months to two and one-half years. Of those treated by mercurials alone, three improved, two were unimproved, and ten died. The ten cases treated with salvarsan showd a mortality of only two; all the other cases were decidedly improved and showed marked gain in weight and improvement in general condition in addition to the disappearance of their specific symptoms. Dr. LaFetra concluded that while the method of giving salvarsan to the nursing mother was valuable and should be used when the mother was available, the surest method consisted in giving the salvarsan to the infant and that both direct and indirect methods should be used where possible. The dosage should not be less than 0.01 grams per kilo weight. Repeated injections and supplemental treatment by mercurials might be necessary. The Wassermann reaction should be followed for one year.

Dr. Butterworth said that only those who had tried to enter the veins of the upper extremities realized the difficulties and he advised the use of the vein over the internal malleolus which had given very satisfactory results. The repeated injections of small doses of salvarsan was better than the giving of the larger doses. The simplicity of the apparatus presented commended itself to him.

Dr. Fritz B. Talbot of Boston said that from the experience of Dr. Vincent of Boston with transfusion he had found that injections into the jugular vein was the most practical of all. In ten cases that had come under his observation there was no trouble when the injection was made into this vein.

Dr. Isaac Abt of Chicago asked how old the children were.

Dr. L. E. LaFetra replied that their ages ranged from six weeks to two years, one child being five and one-half years of age. The apparatus presented possessed the advantage of permitting several injections to be given at the same time. The use of the glass tube was undoubtedly a great advantage, as the fluid could flow through it with greater facility.

A Specimen and Radiograms of a Case of Chondrodystrophy.—Dr. L. E. La Fetra reported this case, and presented specimens and radiograms. The child was admitted to the hospital when a day old and died a little over two months later. The autopsy gave the anatomical diagnosis of chondrodystrophia congenitalis and rachitis. The anterior fontadelle was five c.m. wide and six c.m. long. The sutures were wide open. There was a marked rachitic rosary, the swelling being most marked in the inside of the thorax. There was no Harrison's groove, but a longitudinal groove just external to the costochondral junction. The xiphoid cartilage was bifurcated. The left lung was atelectatic. The heart lay to the right, the aorta being visible and to the right of the pulmonary artery. There was a small patent foramen ovale. The thyroid gland was small. The foramen magnum was very narrow and the clivus was steep. The radiograph showed all the essential bony and joint changes characteristic of achondroplasia. There were no points of ossification for the epiphyses of any of the bones of the upper extremities, but the lower epiphyses of the femur were partially ossified. The diaphyseal ends of the bones were broadened.

The Influence of Milk Stations on Infant Mortality.—Dr. Samuel S. Adams of Washington, D. C., read this paper. He described the milk stations in Washington and said that during the past season they had distributed 322,400 bottles of milk to 213 infants and the total number of cases lost from all causes was 29. He had also given a course of sixty lectures on the care of infants. The total attendance to these lectures was 2,034. Cash prizes were given to young people for the best essays on these lectures. Other prizes were given for attendance and good behavior. Owing to the benefaction of Mr. George M. Oyster, who had made this work possible, the mortality of infants in Washington had been reduced markedly in contrast with that of the rest of the District of Columbia.

Dr. Rowland G. Freeman of New York said there was undoubtedly a great reduction in infant mortality after the establishment of milk depots. This reduction could not be accomplished by education alone. In certain communities in France the infant mortality had been reduced 60 per cent. by the establishment of milk depots.

Dr. J. H. Mason Knox, Jr., of Baltimore said that the statistics given by Dr. Adams corresponded to theirs. There was one feature of the work that had not received the attention that it should and that was the visits to expectant mothers. They had endeavored, therefore, to get into touch with obstetric clinics. The results of one year's work at the Hopkins Clinic, where they had experience with over 500 babies and mothers, was a mortality of only 5 per cent. Fifty per cent. of these were colored people. Of these 40 per cent. were illegitimate children and 60 per cent. of these were entirely breast fed as the result of prenatal instruction. As pediatricians they should encourage better obstetrics.

Dr. Henry L. Coit of Newark, N. J., said he wished to emphasize the point that the nurses employed in this social and educational work should be well trained and well educated, with good judgment and with experience in handling the young. He had such a nurse in Newark and as a result of her work among 515 babies they had obtained a mortality of only 2.7 per cent. Dr. Coit agreed with Dr. Freeman that it would be unfortunate to swing to education alone rather than the dispensing of milk; both were of great value and should be used conjointly.

Dr. Samuel S. Adams of Washington, D. C., said in closing the discussion, that one of the first things to be done was to educate the people in the care of the milk. In their milk stations he insisted that the doctors should be familiar with modern methods of infant feeding. Patent foods were barred but they were permitted to use cereals in combination; otherwise they were not handicapped. Some of the doctors preferred raw milk and some pasteurized. The matter of prenatal visits belonged to obstetrics rather than to pediatrics. Dr. Adams laid emphasis on the importance of the nurses being firm with the people and called attention to the advantage of having attractive nurses as they impressed the parents more favorably.

Election of Officers.—*President*, Dr. John Lovett Morse of Boston; *Vice-President*, Dr. John Rurãh of Baltimore; *Secretary*, Dr. Samuel S. Adams of Washington, D. C.; *Treasurer*, Dr. Chas. Hunter Dunn of Boston, Mass.; *Recorder and Editor*, Dr. L. E. La Fetra of New York; *Representative of the American Pediatric Society, Committee on Arrangements for the meeting of the Congress in Washington, D. C.*, 1913, Dr. Samuel S. Adams. Place of meeting, Washington, D. C.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 16, 1912.

Dr. William M. Polk, in the Chair.

This meeting was held under the auspices of the Section on Ophthalmology.

Relationship of So-called Gastrointestinal Autointoxication to the Etiology and Treatment of Certain Ocular Disorders.—Dr. G. E. de Schweinitz of Philadelphia said that because certain ocular disorders, notably those of the uveal tract, the episclera and perhaps the cornea, existed without our ability satisfactorily to determine the etiological factors, syphilis, tuberculosis, injury, and direct infection having been definitely excluded, and because within the last few years it had been the endeavor of certain investigators to bring some of the diseases in relationship with autointoxication, and because this had led to an animated controversy at present going on, particularly in foreign journals, and because the examinations in many of these instances have been insufficient to prove the presence of a gastrointestinal autointoxication, it seemed to him worth while to recite his personal experience in this matter, and incidentally to refer to some of the recent literature. After a description of the elaborate analyses to which the urine, feces, and stomach contents of the examined patients were subjected, Dr. de Schweinitz summarized the factors which justified a diagnosis of gastrointestinal autointoxication. He dwelt particularly on the quality and character of the urine, especially upon its quantitative analysis, and upon the percentage of ammonia nitrogen to the total nitrogen, upon the fatty acids, and upon the relation of the conjugate sulphates to the total sulphates. Full reference was made to the presence of acetone, urobilin, phenol, and indican, and the opinion was expressed that indican was much overrated as an index of gastrointestinal autointoxication. Dr. de Schweinitz next recited the literature pertaining to this subject from the ocular standpoint, and particularly referred to the efforts of some investigators to bring autointoxication gastrointestinalis into etiological relationship with certain eye diseases, making special reference to the recent papers of Elschnig, von Hippel, and Steulp. Next a summary of the results of the examination of twenty-three patients, with various ocular diseases, chiefly of the uveal tract, was presented, the analyses having been made according to the most improved methods, some of them by Drs. Edsall and Fife, but most of them by Dr. Edward Goodman. The effect of treatment of these patients under the influence of dietetic regimen, worked out according to the results of the analyses, was described, as was also the probable influence of other factors. In all of these patients syphilis, tuberculosis, injury, and direct infection had been eliminated by careful clinical and laboratory methods. He concluded his paper as follows: "First, indicanuria alone must not be taken as the index of an autointoxication proceeding from the gastrointestinal tract, and the potency of this substance as an index of such intoxication, in the asbsence of any other tests or findings, was practically valueless. Second, if the question be asked whether there was any known disease of any of the histological systems of the eye which of itself would justify the inference that an intestinal autointoxication was present, the answer must be "no." In the first place, there was no certain knowledge of any specific intoxication depending upon the nonelimination of metabolic products, and in the second place, the clinical pictures of ocular diseases, for example, of the uveal tract, might be identical although their etiology might be widely different. Third, if the question be asked whether laboratory examinations had isolated any definite toxin to the influence of which could be attributed any of the ocular disorders to which reference had been made this evening, the answer must be "no." If such a criterion of diagnosis of autointoxication was necessary, then none of the ocular disorders described this evening could be regarded as expressions of metabolic disturbance. Fourth, these answers being negative, one naturally inquired was it worth while to make a study of patients with various eye diseases, particularly those of the uveal tract, when the usual etiological factors, syphilis, tuberculosis, etc., were absent, according to the methods described. To this question an affirmative answer might be given. Thoroughly appreciating the fact that the diagnosis of autointoxication was one at which many clinicians look askance, he felt that much of the opprobrium was partly due to the loose and inconsequential manner, as Dr. Goodman put it, in which the term had been employed, and in which the diagnosis had been made. It went without saying that in using the term gastrointestinal autointoxication reference was made to substances which were formed under the influence of vital processes of the organism, and that autointoxication by infection, by the resorption of the products of cryptogenetic infection, and by the absorption of alimentary poisons, meat, sausage, fish, etc., was not to be considered as an autointoxication. But surely the careful analyses to which these patients had been subjected put them in possession of the evidences of intestinal putrefaction, and through them they became acquainted with the patient's nitrogen metabolism, and were enabled under these circumstances to make regulations in diet, strictly scientific regulations in diet, which, whether directly or indirectly, accomplished good. This had been proved many times when prior to these examinations, although the usual remedies for the relief of the diseases under consideration were utilized, the results were indifferent. What the writer insisted upon was that certain uveal tract and corneal affections should be sharply separated from the perfunctory examinations which they had only too often received and from the equally perfunctory and inefficient therapeutic measures which had

been accorded to them. He could not believe that there was any mistake in thoroughly examining a patient, and he could not believe, even though no one had yet been able to prove that autointoxication gastrointestinalis was directly responsible, for example, for uveitis, as was the toxin of syphilis or the toxin of tuberculosis, that it was entirely without influence, or that the restoration to the normal point of a previously deranged metabolism was without its good influence from the therapeutic standpoint. Moreover, he was convinced that such work as Edsall and he, himself, had done nine years ago, and such work as Elschnig, frankly acknowledging the imperfections of his chemical studies, had performed, as well as the later much more thorough studies that had been made by Fife, Goodman and myself, had been of definite value. Elschnig in his most recent communication fully recognized the need of more exact analyses in order to prove his point, and he had started one of the young internists of his clinic in a more thorough examination of cases of relapsing uveitis from this standpoint. If this sort of work was pursued, and he trusted that it would receive attention, it was possible that they might ultimately separate from the large group of relapsing uveal tract diseases a certain number which, if they were not actually caused by autointoxication, which certainly had not been proved, at least occurred in the subjects of this state of affairs, and yielded when under proper dietetic regimen only properly worked out as the result of such analyses, restoration of a normal metabolism.

Furthermore, since many of these diseases, particularly those termed uveitis and iridocyclitis, were distinctly relapsing in character, it was just possible that in some vague way autointoxication might be a determining factor in the relapse. He was not sure that this might not be the chief value which accrued from these studies. Even if certain types of uveal tract diseases which laboratory and clinical tests failed to connect with the usual etiological factors were not directly caused by a gastrointestinal autointoxication, their relapses might be fostered or stimulated by this condition. In a number of instances he had noted that when the strict dietetic regimen was dropped, as, for example, it was by the patient with sclerokeratitis, a sharp relapse ensued. When the analyses indicated a return to normal conditions under dietetic treatment the relapse subsided, and as long as the patient strictly adhered to the diet, or as long as there was no re-establishment of the symptoms which were supposed to indicate autointoxication, relapse did not occur. Unfortunately for his theory, this did not hold good in all cases, as he had seen sharp relapses while the diet was being strictly pursued and the urine analysis was normal. He referred to the matter only because it showed how much careful study must be given to this subject, and how, if it was given, it was possible that they might carefully narrow down a small but none the less definite group of uveal tract disorders, which in some way depended upon an autotoxic state enterogenous in origin. So much had been found out by chemical examination, both in matters etiologic and therapeutic, that he pleaded for this method of examination when it seemed to be necessary, and especially when they were in the dark as to what was causing the particular ocular disease under consideration. To be sure (to quote from Alonzo Taylor) to estimate properly any concept of autointoxication the rôle of compensation and of adaptation in physiological and chemical function must be borne in mind, and they must not expect autointoxication with all disturbances in metabolism, but when autointoxication was apparently proved to be present by such chemical examination as had been described, then it seemed to him that they had found something for removal, and with this removal had gained a point in therapy which it was the patient's right to receive.

Dr. Emil Gruening said that Dr. de Schweinitz was doing a great service to medicine in combining clinical work with laboratory research. The laboratory of physiological chemistry of the University of Pennsylvania was at his disposal and Dr. de Schweinitz was making good use of his unusual facilities. If he had not yet demonstrated the relationship of so-called autointoxication to the etiology of certain ocular diseases, it was due to the difficulty of solving so intricate a problem. His criticism of the work of Elschnig and others who based their reasoning on the presence of indican in the urine was just, but in these critical views he had been preceded in Germany by Eugen von Hippel and O. Stuelp. If in a given case of iridocyclitis we excluded the most frequent etiological factors, viz., tuberculosis and syphilis, we still had to consider a multitude of causative possibilities such as rheumatism, gout, gonorrhea, disease of the accessory sinuses of the nose, etc., before one could have recourse to the vague conjecture of the existence of intestinal autointoxication.

Dr. Colman Ward Cutler said he would not attempt to trespass on the ground so admirably covered by Doctors de Schweinitz and Goodwin. A case of uveitis might be cited, however, which would illustrate some of the difficulties the oculist faced. A colored man, 28 years of age, presented himself with an acute uveits: vitreous opaque, posterior surface of cornea covered with fine opacities, vision 10/200. Blurring of vision was first noticed a week previously. With indifferent treatment (aspirin in moderate doses and a culture of lactic bacillus twice daily) he improved rapidly, and in a month vision became normal and it was possible to see the exudate and edema in various parts of the retina with two patches resembling the so-called plastic choroiditis. The examination of the urine had been negative with the exception of excessive indican. When first seen there were three small suppurating foci at the margin of the lower lid of the affected eye. This case was by no means unusual and without the most thorough investigation it would be impossible to say whether it was an infection or an intoxication. It seemed to him like the former. They saw cases of uveitis, however, which were less acute and appeared more of an irritative than an inflammatory type (if the distinction might be made), where no focus or source of inflammation could be found. It would be interesting if Dr. de Schweinitz could, in his large experience, offer some suggestion for classifying these cases. With regard to the etiology, it might be well to consider anaphylaxis as a possible factor in intoxication. The suggestion of increased sensitiveness as a factor in the causation of phlyctenules was worthy of consideration in these obscure eruptions of the uveal tract.

Dr. Edgar S. Thomson said that he had very little to add to the discussion except his personal impressions which were the results of following the line of treatment suggested by Dr. de Schweinitz in his paper on "Autointoxication," which he read six years ago, before the American Medical Association. He had been in the habit of carefully regulating the digestive conditions, so as to eliminate this cause, and believed that in many cases of choroiditis, autointoxication played an important part. Certainly, the cases cleared up more rapidly under treatment of the gastrointestinal tract, than under other methods. He was of the impression that many cases of so-called rheumatic iritis, also certain forms of episcleral inflammation at the corneal margin, were due to this cause, and thought that the whole subject merited further investigation.

SECTION ON MEDICINE.

Stated Meeting, Held May 21, 1912.

Dr. Walter I. Niles in the Chair.

Fatal Pneumothorax Following Exploratory Puncture.—Dr. Hughes Dayton reported these two cases. He said that in a paper read before the Section in October, 1911, the statement was made that the importance of pneumothorax after exploratory puncture depended upon the condition of the patient at the time of its occurrence and upon the physical state of the perforated lung, which might permit contraction of the puncture or favor extreme or progressive pneumothorax. Since that time two fatal cases had forced the conclusion that the physical state of the opposite lung might be of even greater importance. The first patient was a woman, 58 years of age, the only significant point in whose history was a chronic cough which had persisted for many years. In February, 1911, she was treated for an attack which was diagnosed as pneumonia. She became ill again December 29, 1911. Over both lungs there was a slightly woody resonance, high pitched voice and occasional sibilant and crepitant râles. Posteriorly over the left base, where consolidation had been present the year before, there was impaired resonance and diminished breathing. Six specimens examined for tubercle bacilli were negative. The urine was that of chronic interstitial nephritis. On February 22 the left chest from the seventh rib to the base and extending out four inches from the median line showed dullness and many subcrepitant râles; over the upper part of this area were bronchial breathing, voice, and whisper. Two days later the writer noted signs suggestive of a cavity which within a few minutes after coughing disappeared completely. On March 5, aspiration of the right chest was ordered. The needle was inserted in the sixth right intercostal space just internal to the vertebral border of the scapula. The needle was carefully inserted about one inch and nothing was obtained. The patient complained of intense pain at the site of the puncture after the withdrawal of the needle. She then showed severe and increasing dyspnea and cyanosis. Signs of subcutaneous

emphysema appeared over an area three or four inches in diameter around the site of the puncture. Over the entire right chest were dull tympany and very distinct breath sounds. The right border of cardiac dullness was displaced from the right to the left sternal margin. The patient failed to respond to stimulation, the note over the right chest becoming more dull and losing its tympanic quality. Death ensued. The autopsy showed the diaphragm extending to the fifth space on the right side and to the fourth on the left. The right lung seemed collapsed in part and the heart was displaced to the left. The right pleural cavity was dry. No evidence of a puncture of the lung was found, but besides signs of adhesive pleurisy and right pneumothorax, chronic pleurisy and chronic fibroid phthisis with cavity formation in the left lung were found; other lesions included those of interstitial nephritis, chronic interstitital splenitis, perihepatitis, fibrous goiter, and a calcified uterine fibroma. Although no puncture hole could be found, a small perforation by the needle seemed proven by exclusion. Operation upon the chest would have been ineffective because the asphyxia was due to the collapse of the only serviceable lung. The chief object in reporting this case was to emphasize the danger that existed in puncturing cases in which chronic inflammatory processes were present. A second case of fatal pneumothorax following exploratory puncture was that of a man, 39 years of age, who was suffering apparently from lobar pneumonia involving the right lower lobe. Signs of consolidation of the right lower lobe and the apex of the upper lobe persisted, especially near the spine of the scapula, where they suggested an interlobar empyema. Signs of a suppurative process in the left shoulder developed and an abscess was drained through the deltoid muscle. The *x*-ray showed infiltration of much of the right lung and signs of consolidation became more marked. A needle was inserted in the upper portion of the left chest posteriorly in search of other collections of pus. A few minutes after this puncture the patient complained of a choking sensation and became dyspneic with profuse sweating. Physical signs of pneumothorax developed and the patient died from asphyxia. At autopsy, universal thick pleural adhesions were found over the right lung, which was filled with innumerable tubercles. The apex of the left lung contained many tubercles and the overlying pleura was adherent. The rest of the lung was collapsed. The site of the puncture was not found, but was probably in or near the adherent pleura. As in the first case, it was almost incomplete disability of the unwounded lung which led to the fatal termination from pneumothorax. The point that these cases emphasized above all was that the most serious and sudden results of the occurrence of pneumothorax due to exploratory puncture followed injury, not of the diseased, but of the efficient lung, when, as in the two cases, the diseased lung was so incapacitated by consolidation and adhesions as to be incapable of adjusting itself to the unusual task. The conclusion seemed inevitable that in the presence of probable chronic inflammatory disease of the lung, exploratory puncture should be restricted to cases in which there were good reasons for suspecting the existence of purulent exudate which would require surgical treatment.

The balance of the evening was devoted to contributions from the wards of the second medical division of Bellevue Hospital.

Metabolism Studies on a Case of Typhoid Fever Complicated by Glycosuria.—Dr. Warren Coleman and Dr. E. F. Dubois reported this case. The patient was twenty-seven years old and of obese habit. There was nothing new to be learned from the histories of the parents, brothers, or sisters. In his own history there was nothing that pointed to the fact that the sugar was more than temporary in the urine. Charts were shown of the temperature, weight, and food curve as well as the heat production. There was nothing special to be said in regard to the temperature. The weight curve fell during the fourteenth and twenty-eighth day. It was an interesting fact that sixty calories per day was not sufficient to sustain the patient in weight equilibrium. What he wished especially to call attention to was that the retention of water was responsible for the sustenance of the weight. It was very difficult to hold patients in a nitrogen equilibrium. The nitrogen balance was markedly irregular in the nitrogen excretion. The amount of sugar excreted corresponded very well with the amount of carbohydrates the patient received. An interesting point was that they must assume that it was not the amount of carbohydrates the patient received that was responsible for the glycosuria. Among fifty cases that had been carefully studied there had occurred no acidosis and no acetone bodies had appeared.

Observations on a Case of Paroxysmal Hemoglobinuria.—Dr. Robert A. Cooke presented this communication. He said that in 1904 Donath and Landsteiner attributed the attack characteristic of the disease to a specific hemolyzing substance in the blood of these patients and they demonstrated its presence by experiments *in vitro*. Since that time a number of observations had been made by different investigators, all of whom confirmed the presence of the antolysin, but with regard to the mode of action of this substance there was no unanimity of opinion. The following case was studied with a view to clearing up some of the disputed points. The case was a typical one of paroxysmal hemoglobinuria in a man without history and with none of the stigmata of congenital or acquired syphilis, but with a positive Wassermann reaction and positive Inetin test. The writer considered the hemolysin under the following headings and described his experiments: 1. Demonstration of the autohemolysin. 2. Absorption of the autoantibody from inactive serum. 3. Dissociation of corpuscle antibody combination. 4. Absorption of complement from active serum. 5. Action of complement on red blood corpuscle sensitized with inactive hemolytic serum. 6. Mode of action of the autohemolysin. 7. Etiology of paroxysmal hemoglobinuria. He summarized the results of his experiments as follows: The serum contained a complex hemolysin capable of dissolving the red blood corpuscles of the individual himself or other individuals by means of the cold-warm experiment. Positive results were obtained in all of the twelve experiments made at different times. Autoantibody was absorbed from serum in the absence of complement and on elevation of temperature was more or less completely but slowly dissociated. Complement was absorbed from active serum on exposure to the corpuscle in the cold. It would join with the antibody after the latter had united with the corpuscle, but this union took place solely under the influence of cold. Corpuscles sensitized with inactive serum showed slight hemolysis on the addition of complement as a result of complementoid inhibition. As a result of clinical observation, the Wassermann reaction, the luetin test, and the serological studies in metasyphilitic disease, it seemed safe to say that syphilis was the most important, and perhaps the only, etiological factor in paroxysmal hemoglobinuria, but there were as yet no observations on the presence or absence of the hemolysin after the disappearance of the Wassermann reaction as a result of syphilitic treatment. The case under observation still had a Wassermann reaction, but the writer hoped to report later on this point when the Wassermann reaction had become negative.

Coarctation of the Aorta.—Dr. M. Goodridge reported this case. He said that by coarctation of the aorta was meant a narrowing or stenosis of the descending arch at or immediately below the so-called isthmus of the aorta, that portion of the aorta between the origin of the left subclavian artery and the ductus arteriosus. In extreme cases of stenosis the blood supply of the extremities was dependent upon the establishment of the collateral circulation, and necessarily if the construction was marked this collateral circulation would depend upon the compensatory dilatation of the vessels arising at a point above the stenosis and their anastomoses with vessels arising from a point below the narrowing. In 1903 Bonnet described two types of this condition, the infantile, in which there was a diffuse narrowing of the aorta which was often associated with a patent ductus or other congenital cardiac anomaly, and the adult type characterized by an abrupt constriction of the aorta at or near the insertion of the ductus arteriosus and associated with the development of an extensive collateral circulation. The case reported was of the latter type. On January 29, 1912, a man, 55 years of age, was admitted to Bellevue Hospital whose family history was negative and who had had no serious illness since childhood. The patient admitted a soft chancre twenty-two years ago but denied syphilis and gonorrhea. The patient said that he used alcohol in moderation and tobacco to excess. About one week before admission he began to suffer from palpitation and severe dyspnea on exertion, which increased in severity up to the time of admission. The patient was small of stature and weighed only one hundred pounds. He was mentally defective, his speech being at times unintelligible. The most striking thing revealed by physical examination was the surprising dilatation of the surface vessels in the neck, over the front of the chest, the upper part of the abdomen, and the back. Two inches below the costal margin in the left hypochondrium there was a considerable mass of varicose, dilated,

pulsating arteries. The picture that the back presented was even more striking than that observed over the chest. The posterior scapular arteries on both sides were tremendously dilated, being almost the size of a lead pencil. On the left side there was a mass of tangled, varicose, pulsating arteries forming a clump about two inches in diameter. Over the lower part of the thorax behind several large tortuous vessels were seen extending from the internal border of the scapular to the spinal column, compression of which brought out the fact that the blood was flowing through them toward the aorta instead of in the normal direction. The dorsal branches of the aortic intercostal arteries could be distinguished to the level of the tenth rib on the left side and to the eleventh rib on the right. In these vessels as well the blood was flowing toward the aorta. The apex beat of the heart was not visible. On percussion the left border of the heart was made out 12.5 c.m. from midsternum, the right border 4.5 c.m. to the right and the upper border in the second interspace on the left side. On auscultation the first sound at the apex was obscured by a soft murmur which extended through systole and which was transmitted to the left as far as the midaxilla; at the base a soft systolic murmur was heard, the point of maximum intensity being in the third interspace 4 c.m. to the left of the mid-sternal line and transmitted down the sternum to the apex; the second aortic was accentuated. A loud murmur, systolic in time, was made out along the inner margin of the left scapular behind. The respirations were Cheyne-Stokes in character, the period of dyspnea lasting for twenty-five seconds and the period of apnea thirty-five seconds. Tactile fremitus was diminished, the percussion note was boardy in character over both sides of the chest in front and behind, the breath sounds were diminished, and there were a few moist râles at the end on inspiration over both bases. The radial arteries were thickened, the pulse being 80 during the period of dyspnea and 54 during the period of apnea. The blood pressure in the left arm was 185 millimeters during apnea and 210 during dyspnea; in the left leg it was 170 during apnea and 200 during dyspnea. The blood pressure was higher in the arm than in the leg, which was the reverse of the normal. No pulsation could be made out in the abdominal aorta. Pulsation in the femorals was barely perceptible; the upstroke was distinctly slower and appreciably delayed as compared with the radial arteries. The liver was palpated eight c.m. below the free border of the ribs and the spleen also was palpable. The patellar reflexes were exaggerated, but there was no ankle clonus and no Babinsky. There was a fine tremor in the hands. A clinical diagnosis was made of coarctation of the aorta, hypertrophied and dilated heart, arteriosclerosis, emphysema, and chronic nephritis.

The Effect of Meteoric Conditions on the Vascular System.—Dr. B. Raymond Hoobler read this paper. He called attention to the fact that for some time past weather conditions were becoming more and more recognized as important etiological agents and were receiving more study both from climatologists and from experts in ventilation. The factor in weather conditions most largely studied was that of barometric pressure. B. P. Pomeroy (*Interstate Medical Journal*, Vol. 18, page 731) had recently studied the literature and added his own observations on the effect of barometric pressure on the blood pressure and stated that "The results of nearly all experimental data showed that diminished barometric pressure lowered blood pressure." C. F. Gardiner had shown conclusively that persons changing from an elevation of six thousand feet to one of fourteen thousand feet experienced a fall in blood pressure and a rise in pulse rate. Schneider and Hedblom working with an Erlanger instrument noted that considerable elevation in altitude, that was, in regions of lower barometric pressure, tended to lower systolic and diastolic blood pressure and increased the rate of the heart beat. The fall in systolic pressure was slightly greater and more certain to occur than the fall in diastolic pressure. Another important factor was the relative humidity of the atmosphere. Collis and Penbrey had reported on the effect of warm, humid atmosphere on man. They did their work in the English cotton weaving sheds, where a warm, moist atmosphere was required. They found that the temperature gradually rose from 68° to 101° F., that the relative humidity remained about the same, that the actual humidity was greatly increased; under these conditions the pulse rate increased from 80 to 118 and respiration from 18 to 29. In another experiment in which the atmospheric temperature rose from 70° to 92° F. and relative humidity from 51 to 82 per cent., there was an increase in pulse rates from 80 to 102. These experiments were made on the weavers, both at work and at home resting, and they showed marked variations in pulse rates, in some instances increasing as many as 34 beats during the working period, the temperature of the weaving shed being ten degrees warmer than at home and the relative humidity but slightly increased. Their findings showed that warm, moist atmosphere had a tendency to establish a more uniform temperature of the body as a whole and to throw a tax upon the powers of vascular accommodation as indicated by the low blood pressure, notwithstanding the rapid rate of the pulse. Open air also had a decided effect upon the normal individual. P. P. Aminet examined a large number of healthy children from seven to fifteen years of age in an attempt to find out the influence of outdoor life on the pulse and blood pressure. He found that children living out of doors showed an increase in blood pressure in some cases as much as thirty millimeters of mercury. In only seven out of 140 was there a decrease in pressure. The rate of the pulse was increased by outdoor life. Children living in good surroundings had in general higher blood pressure than those in poor surroundings. These findings were in keeping with the result obtained by the writer in studying the effect of cold fresh air on the blood pressure of children suffering from tuberculosis or pneumonia. L. S. Peters in referring to the effect of temperature on blood pressure said that apparently the higher the temperature the lower the blood pressure, but the writer had found that the converse was true, namely, the colder the temperature the higher the blood pressure. Another meteoric element was that of wind pressure. Starling in a recent communication to the *British Journal of Physiology* (Feb. 17, 1912) stated that a cold wind had a definite influence in raising the pulse rate and that this effect might be so distinct that variation in the wind might be recognized even in individual counts. A number of individuals standing in the wind with a temperature of 44° F. had an average pulse rate of 87.2, while the same individuals in shelter had an average pulse rate of 77.6, a difference of ten beats per minute. Similar tests were made with a number of different groups and all showed the same difference and led to the conclusion that the effect of continued exposure to cold wind or the movement of the body through cold air might be progressive. For example, during a ride in an open car the pulse rate was found to mount gradually from 90 to 100, to 112, to 120, in the course of one and one-half hours' ride. The writer had studied the effect of barometric pressure, temperature, and wind pressure in relation to the occurrence of cerebral hemorrhage, basing his findings on cases that came to autopsy, taking the meteorological records of the United States Weather Bureau. The barometric pressure in New York City varied from 30,924 to 28,420 inches. When estimated in terms of altitude this represented 2,500 feet. In other words, patients might be living at sea level atmospheric pressure and within the space of a few hours be changed to the atmospheric pressure of a mountain top and *vice versa*.

Demonstration of Some Micrographic Tracings.—Dr. F. S. Meara and Dr. A. C. Crehore gave a lantern slide demonstration showing tracings recorded by the micrograph, an instrument designed by Dr. Crehore which utilized the phenomenon of the interference of light for registering minute physiological movements and which was demonstrated in detail to the Academy about a year ago. The tracings showed normal phlebograms and cardiograms which detailed, in addition to the usual waves, the valvular events in the heart and registered cardiac murmurs in a number of pathological cases.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held May 23, 1912.

Dr. F. A. Dorman in the Chair.

Intramural Abscess of the Puerperal Uterus. Intraperitoneal Rupture. Hysterectomy and Recovery.—Dr. Antony Hart Harrigan reported this case. The patient had given birth to a male child four days previous to her admission to the hospital. She had had a severe chill, pain in the lower abdomen, fever, cough, and a bloody fetid lochial discharge. Examination showed the uterus enlarged and boggy, reaching to a level half way between the umbilicus and the symphysis. The cervix was soft and dilated about three inches. Upon opening the peritoneal cavity a large mass was found consisting of the uterus and adherent sigmoid colon, occupying most of the pelvis. On stripping the sigmoid colon, a large abscess with necrotic wall was found on the posterior wall of the uterus, which had ruptured into the parametric tissues. The tubes and broad ligaments were clamped and cut at the ovarian ends. The uterus was completely removed, leaving the cervical

stump. The peritoneum over the uterus was necrotic and friable and much hemorrhage occurred, especially at the site of the left uterine artery. The peritoneum was sewn over the cervical stump with chromic gut. No drainage was instituted. There was free discharge of pus from the wound, but under appropriate treatment the wound gradually granulated and the patient finally made a good recovery. The pathologist's report showed that the uterus measured 6 x 8 x 13 cm. It weighed 250 grams. The walls were thickened and the entire left side on the anterior surface was replaced by a large necrotic mass. The left ovary and tube were adherent to the mass posteriorly. The mass showed no connection with the endometrium. Miscroscopically the section showed a large area of complete necrosis. The muscle cells showed extensive round-celled infiltration and well-marked cloudy swelling. Two small areas of focal necrosis were found between the muscle fibers. The blood vessels were markedly congested. There was a moderate amount of new formed fibrous tissue throughout the section.

Dr. F. A. Dorman said that he had seen but one case of the type described in addition to one upon which Dr. Boldt had operated. He asked Dr. Harrigan what the temperature was and if any cultures had been taken.

Dr. Harrigan replied that the temperature ranged from 99 to 103.2° F. Cultures were then taken.

Partial Removal of the Bladder for Carcinoma.—Dr. Robert T. Morris reported this case. The patient was about 50 years of age and had much blood and pus in the urine. A cystoscopic examination made by Dr. H. D. Furniss showed a growth and the question arose as to what was to be done. Finally it was decided to open the abdomen. The bladder was drawn out, split in half, and the right ureter transplanted. The patient now had a sausage-like bladder with a transplanted ureter. The capacity of this bladder was five ounces and the patient could retain her urine for two hours.

Complete Removal of the Urinary Bladder for Carcinoma After Preliminary Bilateral Lumbar Ureterostomy.—Dr. H. D. Furniss reported this case. He had seen the patient, a woman 50 years of age, for the first time on February 19, 1912. Her previous history was negative. She had one child fifteen years of age. Last summer she had first noticed bladder irritation and some hematuria. This cleared up under medication. For three months before seeing Dr. Furniss she had been suffering from painful and frequent urination. She passed urine easier when standing. The patient lost in weight and strength and the urine was very turbid and contained sufficient blood for her to notice it herself. There was some rectal protrusion from straining. A cystoscopic examination showed a more or less smooth rounded mass arising from the right side of the bladder from above and to the outer side of the urethra. At its base it appeared to be about the thickness of a thumb and extended inward for an inch. The trigonum was very red, infiltrated, and thrown into small folds. The case was diagnosed as one of primary carcinoma of the bladder. The patient was not seen again until April 10, when she complained of severe tenesmus of the bladder, constant inclination to void, and rectal prolapse. The urine had become ammoniacal and caused severe burning and eczema of the thighs. Examination *per vaginam* showed a mass about the size of a duck's egg in the bladder region, most of it lying to the right of the median line. On April 12, a bilateral lumbar ureterostomy was done, a ureteral catheter being tied into each ureter. Both ureters were moderately dilated. A silk ligature was placed at the upper angle of each wound, passing through the external coats of the ureter. On the following day the urine from both ureters showed a moderate amount of pus, a few epithelial cells, and a moderate ring with Heller's test. A fistula into the ureter occurred on the left side at the site of the retaining suture. To close this a catheter was left in for several days. This caused an infection of the renal pelvis which was clearing up under treatment with boric acid solution. On April 27, the bladder was moderately distended with boric acid solution and a ligature placed around the urethra. A median abdominal incision was made, both internal iliac arteries ligated, the peritoneum divided in the median line over the posterior surface of the bladder as low as the anterior cul-de-sac, and the bladder was peeled out with very little hemorrhage. When the bladder had been so separated that the only attachment was the urethra, the vagina was opened from above under the urethra and then by continuing the incision around the urethra through the vagina, the whole bladder and urethra were removed. As the operation was almost finished a small opening was accidentally made into the bladder through which some foul fluid escaped. An iodoform drain was placed from the anterior cul-de-sac, through the space from which the bladder was removed, and into the vagina. The abdomen was closed in layers. The wound broke down and there was extensive sloughing of the fascia. Aside from this and the infection of the left kidney the patient had done well. The specimen exhibited showed that springing from the right side of the bladder, above the urethra, was a large growth, the size of a duck's egg, which in the section of the bladder had been so divided that a small portion of the growth was on one side and the larger portion on the other side of the specimen. The specimen had been mounted without removing a piece for microscopical examination, though there was no doubt but that it was carcinoma. No glands were felt in the pelvis at the time of operation.

Ectopic Gestation in an Anomalous Tube.—Dr. M. M. Stark reported this case which occurred in a patient, 27 years of age, who had been delivered of a child instrumentally two years previously. Her menses since that time had been regular and normal until April 13, when she began to bleed three weeks after her regular menstruation. On April 21 she had a very severe attack of pain in the epigastrium, but after being in bed a few hours she felt as well as ever. A mass was discovered the size of the specimen presented. Three days later she had sharp severe pain and went into collapse. The abdomen became much distended and the patient complained of rectal tenesmus. A diagnosis of ectopic gestation was made and an operation performed immediately. A diagram of the specimen was presented which showed the ectopic gestation in an anomalous tube.

The Relation of Athletics to the Reproductive Life of Women.—Dr. Anganette Parry read this paper. She stated that the literature on this subject was distinguished by its paucity of material, giving few statistics or even opinions. It was even difficult to define just what was meant by athletics. There were all degrees of athletics from the moderate careful training under a wise director to the violent stunts of overzealous young women. The writer had communicated personally or by letter with a considerable number of obstetricians, college physicians, directors of physical training in gymnasiums and universities, and with some athletes whose experience could be relied upon. The answers had varied greatly on important points but in the main they were frankly indefinite. The question of sterility had been studied statistically among college graduates and it seemed that it did not depend upon any particular physical training, but rather upon sociological and economic considerations. The change in the life of the people from the simple life about the home to the complex life of the cities and the indoor confinement made a study of the effects of athletics of great importance. One of the best known obstetricians had said that the great need of women to-day, especially of the upper classes, was muscular exercise. If women would not do normal manual labor athletics seemed to be the next best thing. In general the large majority of those consulted on this subject approved of moderate athletics. Even this was indefinite as with some it would include running and vaulting, while others would rigorously exclude them. A few had laid emphasis on the early systematic training in carefully graded educational work, and perhaps the majority objected to so-called violent work at any time. Some had expressed their appreciation of the value of a good foundation in early childhood, if upon it was to be built "that most complex and noble structure, a perfect womanhood." The Japanese began to train their girls at the age of four or five years in their jiu-jitsu and in Japan the women were not weaker than the men. They were carefully and systematically trained so that at puberty most of them did not find it necessary to make any break, but went steadily on without any apparent injury. If our little girls led the unconventional lives of their small brothers without any distinction as to sex until they reached the age of puberty they would arrive at the first great epoch in their reproductive lives well prepared for the change which was to take place. In preparatory and private schools athletic work, games, gymnastics, etc., should be supervised by an intelligent physical educator, each girl having been carefully examined by a physician conversant with the scope of athletics and the effects of specific forms of exercise. The student should have the advantage of a thorough grounding in the physiological facts essential to her highest physical development; she should be fully aware of the inevitable penalties to be paid for carelessness, recklessness, and exercise too violent or stimulating for her individual organization. She should understand clearly what she might and what she might not do during the menstrual period. While a rational amount of activity was most beneficial at

this period, and often invaluable as a therapeutic agent in dysmenorrheas and other pelvic disturbances, immoderate exercise could be safely indulged in only by the exceptional few. High nervous tension during the menstrual period should be avoided. Those who had expressed themselves on the point of intercollegiate games were unanimously inclined to believe that they should be discouraged because it was impossible to suit the time of the contests and preparatory training to the individual girl. The nervous strain in such contests was tremendous and used up more vital energy than most girls had to give. All seemed to agree that moderate athletic exercises between periods were beneficial for girls; some allowed moderate exercise to normal girls during periods as well as between, but believed that violent exercise during periods was dangerous to all women. A few approved of violent work at any time where the girls were in full training. In their anxiety to be always on the safe side they must not deprive the girls of their birthright—the right to enjoy and be benefited by all that sports and exercise could do for them. Often the negations of older people were the result of ignorance. In this athletic age they must face the responsibility of intelligently advising young women and old along athletic lines. Very often this would render drugs unnecessary by substituting far more natural and effective therapeutics. In regard to parturition, among forty answers the opinion was almost universal that the general condition of athletic patients was much better than that of others. As to displacements five out of twenty gynecologists believed that displacements could be caused by violent exercise, especially during the menstrual period. Several stated that the girl who started up pelvic trouble was the one out of training, with relaxed muscles, who suddenly went into rigorous competitive games or contests. One physical and medical director referred to athletic work begun early as prophylactic treatment and believed that existing displacements were lessened under suitable gymnastic work. Ten out of twelve observers were more or less enthusiastic as to the effects of physical training in relation to convalescence after labor. Several testified that these women were better able to nurse their babies. The two most reliable observers, however, reported that nursing was no better in the athletic women. One observer, indeed, wrote that women who did hard daily work were often unable to nurse their babies.

Dr. C. Ward Crampton, Director of Physical Training and Secretary of the Public School Athletic League, said that inasmuch as the Department of Education had to deal with 350,000 girls and young women it had studied the subject of athletics with much care. The physical and social differences between boys and girls were recognized to be of paramount importance in determining what exercises should be given to girls, and the endeavor to adapt boys' exercises to girls had been definitely abandoned. The strenuous athletic competition in which boys naturally indulged fitted them for the strenuous masculine life; the life of women was entirely different and therefore the physical activities in which girls would naturally indulge under normal circumstances were taken as a guide. It was early determined that folk dances fulfilled the conditions imposed by girlhood better than any other procedure. These provided vigorous exercise, happy recreation, and trained girls to be graceful as well. As these dances were mostly of the peasant type the movements were vigorous, involving the larger muscles of the body. The rhythmic jar involved was mild enough not to damage the various sustentacular abdominal ligaments, but just sufficient to strengthen them materially. These two results were of paramount importance. The carefully guarded life of the civilized woman weakened the natural abdominal supports. The wearing of corsets provided artificial support and relieved the anatomical structure of much of its responsibility. The results were weak abdominal ligaments and general ptosis, with their train of gynecological and toxic disturbances. Other games of similar appropriate nature had been introduced and the team element with emphasis on cooperation had been made prominent. Individual competition had been discarded as it was not deemed advisable for the girl to have the almost hysterical responsibility involved in running a hundred-yard dash for the purpose of winning a championship. He did not approve of the tremendous jar involved in the running broad jump. On the other hand they encouraged long walks into the country and trained their girls to swim well. He did not believe that violent or dangerous feats should be introduced into the public schools. It was more important to train their young women to be vigorous and somatically sound rather than to train them to do unusual and strenuous athletic feats.

Books Received.

The Medical Record *is pleased to receive all new publicotions which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Direct Laryngoscopy, Bronchoscopy, and Œsophagoscopy. By Dr. W. Brunings. Translated and edited by W. G Howarth, M.A., M.B., B.C., F.R.C.S. 370 pages; illustrated; cloth; price $5.00 net. William Wood & Company, Publishers, New York.

The Influence of Caffein on Mental and Motor Efficiency. By H. L. Hollingworth, Ph.D. 166 pages; paper; price $1.50. Archives of Psychology, Publishers, New York.

The Theory of Schizophrenic Negativism. By Prof. E. Bleuler. 36 pages; paper; price 60c. The Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

Resoconto Sommario Delle Sedute. VII Congresso Internazionale Contro la Tubercolosi. 45 pages; paper.

Seventh International Congress Against Tuberculosis. Section I, Social Defence; 93 pages; paper. Section II, Medical Pathology and Therapeutics; 109 pages; paper. Section II, Surgical Pathology and Therapeutics; 78 pages; paper. Section III, Etiology and Epidemiology; 58 pages; paper. Congress to be held in Rome 14th to the 20th of April, 1912.

An Index of Treatment by Various Writers. By Robert Hutchison, M.D., F.R.C.P., H. Stansfield Collier, F.R.C.S., and Warren Coleman, M.D. Sixth Edition, revised and enlarged, 1051 pages; illustrated; cloth; price $6.00 net. William Wood & Company, Publishers, New York.

Recent Advances in Hematology. By Walter K. Hunter, M.D., D.Sc. 111 pages, with a colored plate; cloth; price $2.25 net; William Wood & Company, Publishers, New York.

Der Gynäkologische Operationskursus. By Dr. Wilhelm Liepmann. 488 pages; illustrated; cloth; price 24 M. August Hirschwald, Publisher, Berlin.

Immunity. Methods of Diagnosis and Therapy and Their Practical Application. By Dr. Julius Citron. Translated by A. L. Garbat, M.D. 209 pages; 27 illustrations, 2 colored plates, and 8 charts; cloth; price $3.00 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

Diagnose und Therapie der Magen- und Darmkrankheiten. By Dr. Walter Zweig. 502 pages; illustrated; price $4.00. Rebman Company, Publishers, New York.

Nervöse Angstzustände und ihre Behandlung. By Dr. Wilhelm Stekel. 448 pages; paper; price $4.25. Rebman Company, Publishers, New York.

Essai sur l'Anatomie et la Médecine Operatoire du tronc Coeliaque et de ses Branches de l'Artere Hepatique en Particulier. By Dr. P. de Rio-Branco. 828 pages; illustrated; paper. G. Steinheil, Publisher, Paris.

The Care of the Skin and Hair. By William Allen Pusey, A.M., M.D. 182 pages; cloth. D. Appleton & Co., Publishers, New York.

The Care of the Insane and Hospital Management. By Charles Whitney Page, M.D. 155 pages; cloth; price $1.00. W. M. Leonard, Publisher, Boston.

Taschenbuch der klinischen Hämatologie. By Dr. Von Domarus. 201 pages; illustrated; cloth; price 4 M. Georg Thieme, Publisher, Leipzig.

Medicolegal Notes.

Use of Word "Doctor" by Osteopath.—Colorado Rev. Stat., 1908, Section 6069, prohibits the practice of medicine without a license, but declares that the act shall not apply to "the practice of osteopathy when not prescribing medicine or administering drugs." In an action against an osteopathist for practising medicine without a license, the defendant's lawyer and the district attorney filed a stipulation of facts, the defendant admitting that he held himself out to the public as being engaged in the diagnosis and treatment of diseases and injuries of human beings; that he attached the title "Doctor" and the abbreviation "Dr." to his name. The district attorney admitted that the defendant was a graduate from a college of osteopathy, recognized as a reputable institution for teaching osteopathy, that he held a diploma from the college and a certificate from an osteopathic association; that he styled himself "Osteopathic Physician" and at no time had attached the word "Doctor" or "Dr." to his name except in connection with the words "Osteopath" or "Osteopathic Physician," and that he was engaged in the practice of osteopathy without prescribing medicine or administering drugs. It was held that he was not guilty of a violation of the act.—Jones v. People, Colorado Supreme Court, 120 Pac. 125.

Qualification as Expert Witness on Insanity.—In a murder case, where the defense was insanity, a physician called as an expert witness on the subject testified that he was a graduate of a medical school and had been a practicing physician since 1886, but that his experience in the treatment of persons mentally afflicted has been very limited, being covered by two or three cases, and that he had read some works upon diseases of the mind, but could not remember their names. It was held that he was not qualified to testify as an expert on insanity. Another physician, who had practiced medicine about 44 years, but was not a graduate of any school, held no diploma, had very little experience in treating insanity, had never prescribed for a real insane person, had read some books on insane diseases but did not consider himself as well posted on mental diseases as on general diseases, was also held not qualified to testify as an insanity expert.—Ashby v. State, Tennessee Supreme Court, 139 S. W. 872.

When Limitation Begins to Run Against Action for Negligence.—In deciding whether the statute of limitations of one year had run against an action for negligence in unskillfully resetting a broken arm, it appeared that the injury, which was a simple fracture of the radius of the forearm, at about the junction of the lower and middle third, was treated between August 24 and September 26, 1908, but not after the latter date, and the action was commenced on November 13, 1909. The acts of negligence having taken place before September 26, 1908, the mere fact that there was no discharge of the defendant on that date was immaterial. The statute of limitations began to run when the cause of action accrued, and that accrued when the negligent acts were committed, without reference to the time of discharge. The complaint was therefore ordered dismissed.—Lotten v. O'Brien, Wisconsin Supreme Court, 131 N. W. 361.

Liability of Corporation for Its Surgeon.—In an action against a railroad company for injury caused by the malpractice of its surgeon, it was held that the evidence must show either actual knowledge of the unfitness of the surgeon appointed or retained by it, or that his general reputation was so bad that the law will impute knowledge. It is not competent to show specific acts of unskillfulness not brought home to the company.—Atlantic Coast Line R. Co. v. Whitney, Florida Supreme Court, 56 So., 937.

Effect of Party's Refusal to Submit to Medical Examination.—In an action for injuries received in a street car accident the plaintiff had the advantage, on the trial, of the testimony of three physicians of her own selection, whom she allowed to examine her, not only when she was first injured, but at the time of the trial, but she never would permit any physician representing the defendant to examine her at all. When during the trial, the defendant's counsel moved the court to appoint experts for that purpose the plantiff's counsel objected, and the objection was sustained. On appeal it was said by the court, that whether or not that ruling was correct (which it did not find it necessary to decide), the expert testimony for the plaintiff stood upon much the same footing as would that of an expert accountant, named by one litigant, in a case in which the other litigant was denied all access to the account constituting the subject of the litigation.—Grant v. New Orleans Ry. & Light Co., Louisiana Supreme Court, 56 So., 897.

Medical Items.

Kinesitherapy in Mucomembranous Enteritis.—E. Lanel believes that mucomembranous enteritis is essentially a nervous disorder affecting the intestine through the solar plexus. There is a spasmodic condition of the intestine which produces constipation, and this alternates with apparent diarrheal movements in which the scyballæ are mixed with loose feces. Hyperexcitability of the symnathetic system is at the bottom of this condition. Another etiological factor is hereditary arthritism, which in the descendants causes vulnerability of the vascular and nervous systems. Mucomembranous enteritis is, then, a trophoneurosis, secretory and motor, caused by irritation of the sympathetic system. Spasm of the vessels and irregular nutrition of the intestinal walls, accompanied by lack of function of the intestinal glands and liver, cause prolonged digestion and putrefaction of the albuminoids and favors the growth of bacteria in the feces. Irritation causes increase of mucus, pain, and spasm, and one has presented the whole syndrome. In the treatment of this condition one should be guided by the degree of the disease at which the patient has arrived. In slight degrees the treatment consists of simple movements in which the patient's strength is not taxed; these take up the interest and attention; general massage and passive movements are also used. Circulation is improved, cellular nutrition increased, and the function of the glands and muscles is increased. The massage used locally over the abdomen should be very gentle and consist of stroking motions in the line of the colon. As the health grows better open-air sports should be gradually begun. When inflammatory symptoms are present the abdominal massage may be done over the hand of the operator with a vibrator, which has an anesthetic effect on the intestines. Kinesitherapy permits of many forms of graded movements, adaptable to the different conditions of the patient. It allows of active and passive movements, and such as call upon the use of the intelligence and will of the patient, and give a physical reeducation. Thus it is a complete method. —*Annali di Elettricita Medica e Terapia Fisica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 19, 1912:

THE EFFECT OF SPECIFIC TREATMENT ON THE CEREBROSPINAL FLUID.*

BY W. F. LORENZ, M.D.

MENDOTA, WIS.

THE parasyphilitic affections of the central nervous system are invariably accompanied by pathological cerebrospinal fluids. This pathology comprises an increase of the globulin constituent, a lymphocytosis, and less frequently a positive Wassermann reaction. The purpose of this investigation was to ascertain the changes brought about in these three factors after the case had been subjected to an antisyphilitic treatment.

Conflicting reports also have appeared in the literature. Javorski[1] found an alteration in the fluid of paretics following mercurial treatment. He reported a reduction in the number of lymphocytes and likewise in the amount of globulin. Milan and Levy Valense[2] noted a rapid fall in the number of lymphocytes following the use of "606" in cases of tabes and general paralysis. In Brown's[3] report on the use of "606," he speaks of the reduction in the number of lymphocytes though the amount of globulin remained unchanged. Upon the other hand, Ducastel and Paraf[4] found no suppression of lymphocytes in the fluid of paretics as the result of treatment, nor was there a reduction in the case of tabes treated with mercury and three injections of "606" reported by Dufour.[5] Kleinberger[6] found little change in the spinal fluid of paretics or tabetics treated with mercury and potassium iodide. In some of his cases of paresis thus treated the lymphocytes were more abundant following the treatment.

For this investigation I selected nine cases of general paralysis, representing all stages of the disease, and three cases of Huntington's chorea. The treatment employed was the Ehrlich-Hata preparation and sodium cacodylate. To more fairly compare the results of these two arsenical preparations I had to use each in a similar manner. The intravenous method was thought to be the most desirable for the "606," and consequently I had to experiment with sodium cacodylate in order to administer this by the same route.

My report upon the intravenous use of sodium cacodylate is incidental to this paper, and I hope to make a more complete report at some future time. Very little has appeared upon the use of this drug in this manner. L. Anelli[7] gave 0.05 gm. in 1 c.c. of water directly into the vein. Mendel[8] commented upon this mode of administration as being superior to any other. He used one to three c.c. of a 5 per cent. aqueous solution.

*Read at the meeting of the West Side Branch of the Chicago Medical Society, held April 17, 18, and 19, 1912, at Chicago.

The dosage, method, intervals between administration as well as results have been variously reported upon. Dawes and Jackson[9] used sodium cacodylate hypodermically in doses of 0.2 to 0.3 gm. They reported very favorable results in the anemias, neurites, eczemas, neuralgias, and chronic rheumatism. In syphilis Dawes suggests a massive dose of 0.6 gm., and Murphy[10] used it in doses of 0.17 to 0.3 hypodermically in early syphilis with good results. Caffrey[11] reported favorably upon its use in early syphilis. He gave 0.07 gm. deep into the muscle for eight days, doubling this amount, and finaly gave 0.2 gm. Schirrman[12] employed it in gumma of the brain with very favorable results. He gave 0.2 gm. hypodermically. Sugget[13] reported favorably upon its use in early secondary syphilis, hemiplegia, and in congenital syphilis. His method was the intramuscular injection of 0.05 to 0.2 gm. Spivak[14] concluded that it was a valuable adjunct in the treatment of syphilis, the best results being obtained in early cases. He gave it subcutaneously in doses of approximately 0.3 gm. The authors quoted used this preparation in daily administrations. Cragler[15] gave the drug at intervals of two weeks. He used it in tertiary syphilis in doses of 0.05 to 0.1 gm., with favorable results. Cuthbertson[16] reported favorably upon its use in erythema. His method was 0.05 gm. hypodermically every three days. In a recent communication Herzfeld[17] draws attention to his use of sodium arsenite subcutaneously in two cases of syphilis with favorable results.

Those reporting unfavorably upon its use in syphilis are Long[18] and Nichols.[19] The latter showed very definitely that this preparation had no effect upon the spirocheta when used experimentally in rabbits, and could not be substituted for "606."

I began the intravenous use of sodium cacodylate in very small doses. The first four cases received each 0.02 gm. dissolved in 50 c.c. of normal saline. No untoward symptoms were manifested and I rapidly increased the dose until 0.4 gm. dissolved in 100 c.c. of normal saline was given. This was borne without apparent ill effects, although now I first noticed the characteristic odor to the breath. This increase from 0.02 gm. to 0.4 gm. was made in three weeks. In each case four intravenous injections were made. I now attempted to ascertain how long this drug remained in the circulation and whether or not it appeared in the spinal fluid. For this purpose six cases of dementia præcox, showing a mild anemia, though otherwise physically healthy, were given 0.4 gm. of sodium cacodylate by the intravenous method. The first case, "A," was punctured for spinal fluid and for blood twenty-four hours after the administration, the second case, "B," forty-eight hours, and the third case, "C," seventy-two hours. The blood serum, clotted blood and spinal fluid were tested for the presence of arsenic. The Marsh test was employed and was

made by Mr. E. J. Tully of the State Hygienic Laboratory, Madison, Wis. The reports returned were all negative. I then gave cases "E," "D," and "F" 0.8 gm. of sodium cacodylate intravenously and secured specimens of spinal fluid and blood, three, six, and twelve hours after the administration. The urine of this last series of cases was taken by catheter one-half hour after the administration of the drug and subsequently a specimen obtained when the urine was voluntarily voided. The blood serum and spinal fluid were again reported negative. I then took a case ("G"), gave 1 gm. of sodium cacodylate intravenously and punctured for spinal fluid and for blood one hour after administration, again saving the urine for similar tests. This time both the spinal fluid and blood serum showed a trace of arsenic.

TABLE I.—RESULTS OF TESTS FOR ARSENIC IN SPINAL FLUID, BLOOD AND URINE—DRUG USED—MAXIMUM LAST DOSE—METHOD—TIME SPECIMEN WAS TAKEN AFTER DRUG ADMINISTRATION

In all fifty tests for arsenic were made. This includes the cases that were given "606." The amount of material used in each instance for the arsenic test was approximately four c.c. of spinal fluid, fifteen to twenty c.c. of blood, and thirty c.c. of urine. The clotted blood gave the same results as the blood serum so that in the accompanying table "blood" refers to either clotted blood or blood serum.

Table I shows the results of the Marsh test for arsenic in the cerebrospinal fluid, blood, and urine of cases treated with sodium cacodylate and with "606"; the dose, method of administration, and time after administration when the specimen was taken.

If detectable arsenic by the Marsh test can be taken as an indication of the presence of sodium cacodylate or "606" in the cerebrospinal fluid and the blood, one must conclude from the results of these examinations that sodium cacodylate is present one hour after administration, and disappears within three hours. Under the same conditions "606" seems to disappear from the blood within three hours, and excepting Case II, in which a slight trace of arsenic was found in the spinal fluid after twenty-one days, no other serum or spinal fluid gave any indication of its presence. The case reported by Dr. Balzer[20] is likewise an exception to these findings. This was a case of death while under treatment with salvarsan in which the spinal fluid showed the presence of arsenic seven days after the injection of 0.3 gm. of the drug.

The urine shows arsenic in fair amounts within one-half hour after the administration of sodium cacodylate, and in the case of "606" arsenic was found in the voluntarily voided specimen two and three-quarter hours after administration. The arsenic continues present in the cases injected with sodium cacodylate, approximately twenty-eight hours, gradually becoming less marked. In the cases given "606," arsenic continued present in the urine until the fifty-seventh hour, when very slight traces only were obtained.

I would conclude from these findings that sodium cacodylate is very rapidly eliminated and likewise "606," and that both drugs disappear from the circulation within a few hours after administration. The rapidity with which sodium cacodylate is excreted was shown in several cases. Before the intravenous injection was completed, this usually requiring fifteen minutes, in several instances the characteristic odor was detected on the breath. It follows that the daily method of administration, at least in the use of sodium cacodylate, would be indicated, furthermore the safe dose of sodium cacodylate is much larger than that usually given. Two of the cases in this series received 1 gm. intravenously at one dose and another 1.2 gm. in the same manner yet none showed ill effects. Two of the cases received 1 gm. deep into the muscle. This injection was without pain or discomfort. I consider it to be absolutely safe. This experimental work with sodium cacodylate was coincidental to the original investigation and I could not take advantage of the results in the series in which the spinal fluid was to be examined.

The dosage and methods of administration of sodium cacodylate in the cases where spinal fluid examinations were made are as follows: Case I and XI were given deep muscular injections. The first dose was 0.2 gm.; three days later 0.4 gm.; two weeks later 0.6 gm., and eight days following 1 gm. This last dose of 1 gm. was re-

peated the week following; in all 3.2 gm. were given. Cases VI, VII, VIII, IX, XII, XIV, and XV received the drug by the intravenous method. The first dose was 0.02 gm. This was increased, and at the fourth injection Cases XII, XIV, and XV received 0.4 gm., while Cases VI, VII, and VIII received 0.8 gm. Case IX was given 1.2 gm. The solution was prepared by first dissolving 4 gm. of sodium cacodylate in 10 c.c. of distilled water. This solution was brought to the boiling point. The final dilution used for the intravenous injection was in the proportion of 10 mg. to 1 c.c. of freshly prepared normal saline—thus 100 c.c. equaled 1 gm. of the drug.

The intravenous administrations were borne without apparent ill effect and I believe that 1 gm. can be given in this manner with perfect safety. In fact two cases, VII and VIII, in which the drug was used in doses of 0.8 gm., have well defined focal lesions with left hemiplegia. Case VIII, which will again be referred to, is especially interesting.

Four of the original series in whom the cerebrospinal fluid was to be examined received "606." In one case (IV), owing to faulty technique, the first intravenous injection was not successful and he received only 0.1 gm. The remaining three cases received 0.3 gm. Four weeks later three of the original four received 0.5 gm. The first administration was followed within one-half hour by severe vomiting and diarrhea, temperature rose to 104° and 106° and a flush very much resembling scarlet fever appeared. The temperature fell to normal within twelve hours, the flush gradually disappeared, and the vomiting ceased after three hours. Three days after this reaction a pustular eruption appeared upon the lips, which gradually disappeared at the end of a week. This intense reaction was due without doubt to the distilled water not being fresh. The second administration in which 0.5 gm. was given was not followed by any of these symptoms. This time I was careful to use water that was distilled the same day the injection was made.

Sicard and Bloch[21] have claimed that changes in spinal lymphocytosis occur without treatment. My own experience has been that early in paresis the lymphocytosis as well as globulin content is high and that late in its course both of these factors are somewhat less involved. In order to satisfy myself upon this point in the series under examination, I made a second puncture at intervals of three to thirteen months after the initial puncture. During these intervals no antisyphilitic treatment was given, and any change in lymphocytosis or globulin content could be ascribed to the progress of the disease process uninfluenced by treatment. Excepting Case VIII the results obtained at the first puncture do not vary greatly from those obtained at the second.

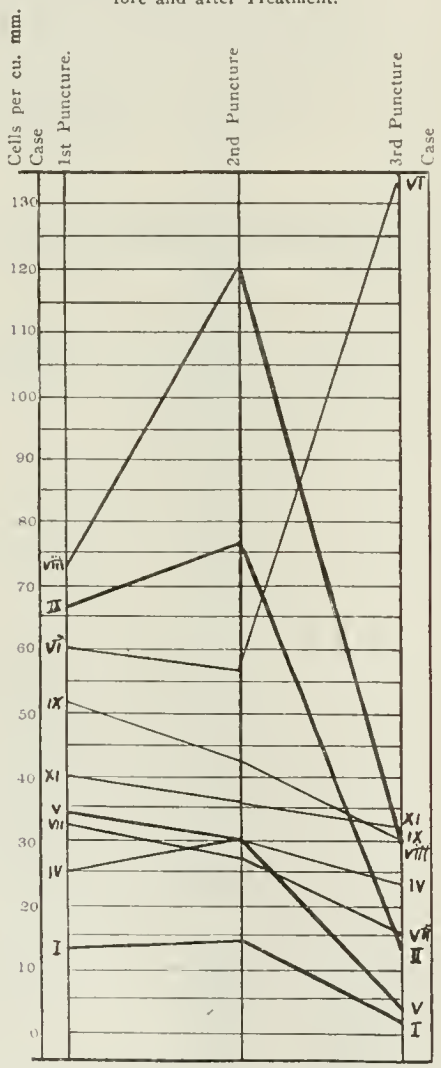
Table II shows the results of the spinal fluid examination at the time of the first puncture, after a specified interval the examination of the fluid obtained at the second, the drug used in each case

previous to the third puncture, and the interval elapsing between the second and third puncture.

The lymphocytosis was estimated by the cell chamber method. The same technique was followed throughout the investigation. As a rule three cu. mm. of fluid were counted and an average taken. The most marked changes occurred in Cases I, II, V, VI, and VIII. Two cases, I and V, showed fluids that from the cytological and chemical examination could be called normal. In Cases II, VII, and VIII, the reduction in the number of cells was very marked. In Cases IV, IX, and XI, the change was less, in fact no greater than may occur during the interval of non-treatment. Case VI showed a marked increase in the number of lymphocytes. This case is one of paresis of over four years' duration. The general trend of the change in the amount of lymphocytes of the spinal fluid following treatment is well shown in Table III.

TABLE III.

Graphic Chart of changes in Lymphocytosis of the Spinal Fluid before and after Treatment.



The globulin content of the fluid was examined for by the Noguchi butyric acid test and the contact test with saturated ammonium sulphate. In the use of the butyric acid test it frequently occurs that the precipitate is unusually heavy and very prompt in its appearance: in other cases the flocculi are fine and the precipitate after settling is considerably less in amount. It has also been observed that the time for the appearance of the characteristic precipitate is in some cases several minutes while in others it appears in less than half a minute. An effort was made to note these types of reaction and it was observed that in several cases the reaction was slower in its appearance and the precipitate was less in amount after treatment. If time of appearance and amount of precipitate can be taken as an index of the relative amount of globulin, it follows that in several cases the pathological increase of globulin as shown by the Noguchi test is materially reduced after treatment. Furthermore this reduction is accompanied by a reduction in the lymphocytosis.

Case I shows a positive reaction to both tests upon two occasions previous to treatment and was negative following the use of sodium cacodylate. Case V changed from positive to negative after the use of "606." The same change was observed in Case VII. In these three cases the most marked reduction in lymphocytosis took place. Cases II, IV, and VIII showed a change in the reaction with the Noguchi test after the medication. While the reaction was positive yet it was slower in its appearance and the precipitate was considerably less in amount. Cases VI, IX, and XI, all well advanced in the disease, showed no change in the character of the reaction with the Noguchi reagents. In two of these (Cases IX and XI) the reduction in the number of lymphocytes was relatively slight, while Case VI showed a marked increase of cells.

At this point special reference must be made to Case VIII of this series. A marked increase of cells occurring during an interval of non-treatment seems to have a special significance in view of the subsequent course of this case. Two days following the intravenous injection of "606" this case developed a complete and well marked hemiplegia. This hemiplegia gradually disappeared although considerable muscular weakness persisted. The case was then given sodium cacodylate also by the intravenous route. The examination of the fluid obtained at the third puncture showed a great reduction in the number of cells and the Noguchi test was slower in its appearance with considerably less precipitate. I am inclined to look upon the sudden rise of lymphocytosis as a premonitory sign of a focal lesion and in this instance would not ascribe the hemiplegia to the actions of "606."

The Wassermann tests reported in this series were made by Dr. W. T. Mefford. He employs the following signs to indicate the degree of reaction: "+" indicates a faint reaction, "++" a weak reaction, "+++" a positive reaction, "++++" a strongly positive reaction.

Specimens of cerebrospinal fluid and blood were examined for the reaction to the Wassermann test before and after treatment. In most of the cases two examinations with the blood serum were made after treatment. With the spinal fluid but one was made following treatment. The results of these examinations are shown in Table IV.

An extremely interesting finding was the positive reaction with the blood serum and spinal fluid of the cases of Huntington's chorea. To my knowledge but one case of Huntington's chorea had been reported upon in this regard. In the series of examinations made by Rosanoff and Wiseman,[22] they included one case of this disease. Their findings were negative. The cases examined in this series showed a positive Wassermann with the blood serum of all three before treatment and with the spinal fluid of one. In two of these cases, XIV

and XV, the Wassermann test was not made with the spinal fluid before treatment; in fact at the time these cases were selected it was not thought that a positive Wassermann was to be entertained in Huntington's chorea. In all three of these cases both acquired and inherited syphilis can be ruled out with a fair degree of certainty and it seems as though this disease must be included with the few other non-syphilitic ailments that occasionally give positive Wassermann reactions.

The change from positive to negative in both spinal fluid and blood serum following treatment occurred in Case I. This case it will be recalled received sodium cacodylate. In Case II the blood serum became positive after the first injection of "606." The final examination with the spinal fluid gave a negative finding while the blood serum continued faintly positive. No change took place in Cases IV, VII, VIII and IX. In Cases V and VI the reaction was negative at all times. In Case XI the spinal fluid was negative following the use of sodium cacodylate. Cases XII and XIV (Huntington's chorea) gave a negative reaction in both the spinal fluid and blood serum seven days after the use of sodium cacodylate, while Case XV (Huntington's chorea) showed no change in the reaction although this case received the same medication in the same manner and same dosage.

The number of cases examined is small and I realize the danger of generalizing from these few cases. The variability of reaction occasionally encountered during the course of parasyphilitic diseases when no treatment has been used must be considered. Upon the other hand the failure of effect of treatment upon the Wassermann reaction has also been frequently mentioned. In short no conclusions will be attempted from the changes that occurred in the Wassermann reaction in this series following treatment.

In briefly reviewing the results of this investigation the conclusion is forced that marked changes occur in the spinal fluid, presumably as the result of treatment. These changes tend toward a reduction in the number of lymphocytes and in the amount of globulin. When paresis is approached from either its histopathological aspect or its general clinical course, these findings should not be surprising. In the first instance the cortical changes accompanying paresis indicate in part a fairly active process while clinically the disease is steadily progressive, and argues the probability of the presence of an active toxin. This in conjunction with about seventy per cent. of positive Wassermann reactions, the latter being claimed by many to mean the presence of spirocheta, favors the contention that paresis and therefore tabes should receive active energetic treatment. It is not thought that degenerated nerves can be made to functionate nor that highly specialized tissue will be replaced by similar kind, yet if the parasyphilitic diseases can be halted early in their course much will have been accomplished.

This investigation is not complete. The cases that showed improvement must again be examined after considerable time has elapsed in order to exclude remissions that are occasionally encountered during the course of the parasyphilitic diseases, yet this significant fact remains—definite changes occur in the pathology of the spinal fluid following treatment. The question as to whether these changes in the spinal fluid indicate a halting in the progress of the disease cannot as yet be answered.

The conclusions resulting from this investigation are as follows:

1. The lymphocytes of the cerebrospinal fluid is reduced following the use of either sodium cacodylate or "606" in early cases of paresis.

2. The excess of globulin in the spinal fluid as shown by the Noguchi butyric acid test is less marked following the use of sodium cacodylate or "606."

3. The lymphocytosis and the globulin content of the spinal fluid tend to parallel one another in this reduction.

4. Sodium cacodylate and "606" disappear from the blood within three hours after administration.

5. Arsenic is present in the spinal fluid and the blood serum one hour after the administration of sodium cacodylate.

6. Following the administration of sodium cacodylate or "606" the urine very soon shows the presence of arsenic, and sodium cacodylate is probably entirely excreted within two days.

7. One gram of sodium cacodylate is a safe dose both by the intramuscular or the intravenous route.

8. Three cases of Huntington's chorea gave a positive Wassermann reaction with the blood serum and two with the spinal fluid.

I wish to acknowledge my indebtedness to Dr. M. P. Ravenel, Director of the State Hygienic Laboratory, Madison, Wis., for the help rendered, to Dr. W. T. Mefford of Chicago for the Wassermann tests, and to Dr. Charles Gorst, Superintendent of the Wisconsin State Hospital, and my colleagues, Dr. M. K. Green and Dr. A. Sauthoff, for their kind cooperation.

EXAMINATIONS OF THE EYES OF COLLEGE STUDENTS.

By M. DRESBACH, M.D.,

ITHACA, N. Y.

FROM THE DEPARTMENT OF PHYSICAL CULTURE, CORNELL UNIVERSITY.

It has become an almost universal practice in the colleges and universities of this country to require a physical examination of entering students, and many institutions require a prescribed course in physical culture extending over one or more years. In making such requirements the schools assume the function of guarding the health of the young men and women during a part or the whole of their study years. In this respect our educational system is unique; but, as might be supposed, the attitude taken towards this subject is by no means the same in all institutions. This fact is shown by the varying extent to which emphasis is laid upon athletic sports at different schools, and by the extremes in the methods employed in examining the students for physical defects. An inquiry into these methods shows that they range from superficial inspections, by untrained persons in charge, to rigid tests and thorough examinations by specialists with a medical training. Until very recently but little careful attention has been given to ocular defects (and still less heed has been paid to ear, nose, throat, and kidney conditions), it having been deemed sufficient to know whether or not the student was sound in heart and lungs, or whether or not he met certain so-called standard tests of measurement and strength. In other words, the physical examinations have often been far from complete, some very important organs having been omitted. It is one of these neglected organs that I wish to consider in this paper, which is based upon facts revealed by the examination of the eyes of a large and representative body of students.

The problem of how to inspect a large body of entering students in the shortest time compatible with efficiency is a difficult one. For the good of the students it is desirable that they should have the complete examination as soon after entrance as possible, preferably within three months after enrollment. Where a thousand or more individuals must be examined, it means, of course, that either a few examiners will work many hours a day for several weeks or months, or that a larger examining force must be secured to complete the work within the desired length of time. At this institution it has been necessary during the past two years to examine from 1400 to 1600 men students and from 200 to 300 women students on entrance. This work has been done by two examiners for the men and one for the women, but during the present year a third physician has been secured for the men in order that certain features of the work might be extended and improved.

The object of the examination.—While my principal duty was to make the eye, ear, nose, and throat examinations, the general object of the entire physical inspection, as conducted at this institution, may be stated as follows: (1) To detect those students who have physical defects or states of health of such a nature that immediate medical attention is advisable, as, for example, in the case of those with cardiac and pulmonary lesions, ocular troubles, infectious diseases, etc. (2) To pick out those with minor defects and faulty development, in order that corrective exercises may be begun. (3) To determine the fitness of candidates for special athletics to go into contests, and to advise such candidates about their physical condition from time to time. (4) To tabulate vital statistics which may be of value.

Objects, methods, and limitation of the examinations for visual defects.—As stated above, it is desirable to have these examinations made as soon as possible after the student enters college, in order that he may have the benefit of the information obtained. The practice here is to require the student to report at once to the physical director after registration in order to make an appointment for the complete physical examination. In this inspection approximately one-half the time is devoted to the eye, ear, nose, and throat tests. The eye-tests have included the following steps, each eye being taken separately: (1) Inspection for external signs of inflammation or other evidence of disease. (2) Determination of visual acuity by means of test letters. (3) Examination for refractive errors, myopia, hyperopia, and astigmatism. (4) Examination for muscular imbalance. (5) Testing of the power of accommodation. (6) Elicitation of symptoms of eyestrain.

In steps 3, 4, 5, and 6, we made use of the trial lenses,* and took into account errors of 0.25 D. or more. Heterophoria of less than 5 degrees was not recorded. By means of well directed questions the history of each student was obtained and noted, and if there were objective or subjective signs of eyestrain; if glasses worn were poorly adjusted or without correction for astigmatism; if the last examination had been made without a cycloplegic or

*The trial frame used was devised by Dr. George M. Gould. It is accurate and permits one to work rapidly.

"drops," or if it had been made more than two years before the student registered for examination at this institution; if lenses worn had been ordered by some optician, optometrist, or "eyesight specialist;" in short, if any suspicion arose that examination by a competent physicain was advisable, the student was so informed. He was also requested to report later as to what he had done about the matter.

In carrying on these tests there have been certain limitations which should be mentioned. First, no cycloplegic was used (as is done at the University of Pennsylvania). While this restriction made it impossible to diagnose accurately the nature, amount, etc., of the refractive error in some cases, it was always possible to decide whether or not a more thorough examination was needed. All cases of doubtful diagnosis were appropriately marked and most of such students were sent to an oculist at once. These cases are included among the "unclassified" in the table below. Secondly, there was the time-limit. The average time given to each student was from 10 to 15 minutes. In some instances this was increased and in particular cases a special appointment was made for more extended testing. Thirdly, the ophthalmoscope was not often used. However, all cases in which inspection of the fundus was indicated were sent to the oculist. In spite of these limitations, the results have been very encouraging and have shown that it is possible for one or two men to examine rapidly a large number of students with a degree of success that justifies the time, labor, and expense devoted to the work.

In the tables below are collected certain data which have been accumulated during the past three years. Many points of clinical and scientific interest have been observed but they could not be brought within the scope of this paper. Thus, to mention only one, the subject of muscular imbalance has not been discussed in any way though it is important. The data given are not presented because they offer anything new, but because they help to emphasize the too greatly neglected factor of eye-strain in its relation to health and happiness, and therefore to efficiency of work. The statistics have been classified in a way that is purely personal with the writer. An attempt has been made to present them in a form which is clear and which will make them available for comparison with others of the kind. The separation of the students into two groups—those wearing glasses and those not wearing them—has no special significance. It simply serves to indicate the number who, for one reason or another, have found it necessary to pay some attention to their eyes. How well this duty has been performed is another matter which must be determined in each separate case. The data are given as percentages, and a word of explanation as to how the percentages are calculated is necessary. The table is divided into sixteen subdivisions in which will be found the numerical values upon which the calculations are based. Thus, for example, the table shows (in division 3) that there were 2161 students who had hyperopic astigmatism, compound or simple, and who did not wear glasses. Of these 2161, 89 per cent. had normal visual acuity. Division 6 shows that 320 (wearing glasses) had myopic astigmatism, compound or simple, and that 50 per cent. of these had a reduction of acuity to between 20/40 and 20/100 (that is, to between 1/2 and 1/5 normal), etc.

Another point that will be noted is that the classification of refractive errors is limited practically to a division into hyperopic and myopic types, though a few figures are given relating to asymmetric and mixed astigmatism, to unequal visual acuity of the two eyes, and to some other matters. This arrangement has been unavoidable for the rea-

TABLE OF STATISTICS.

From Examination of 3326 Regularly Enrolled Men.

The asterisk printed after the numbers in the right hand column indicates that glasses were worn.

Astigmatism—simple and compound.

(1) 2484
Per cent. with hyperopic type 87
Per cent. with myopic type.. 8
Unclassified (including mixed astig., doubtful diagnoses) 3.0

(2) 842*
Per cent. with hyperopic type 50
Per cent. with myopic type..39
Unclassified cases ..... 8 (as in division 1)

Astigmatism (hyperopic type).

(3) 2161
Per cent. with acuity normal in both eyes 89
Acuity subnormal in both eyes 5
Acuity in left eye normal but subnormal in right..... 4
Vice versa 2
Acuity reduced to 20/40 or less in one or both eyes...10†

(4) 427*
Acuity normal in both eyes, 60 per cent.
Acuity subnormal in both eyes, 32 per cent.
Acuity normal in one eye, subnormal in other.. 8 per cent.
Acuity reduced to 20/40 or less in one or both eyes...19

†Percentage calculated from those with subnormal acuity.

Astigmatism (myopic type).

(5) 222
Acuity 20/40-20/100 both eyes, 34 per cent.
Acuity 20/40 or less one eye, 13 per cent.
Acuity 20/100 or less in one or both eyes ..... 4 per cent.

(6) 320*
Acuity 20/40-20/100 both eyes, 50 per cent.
Acuity 20/40 or less in one eye, 6 per cent.
Acuity 20/100 or less in one or both eyes .....2-3 per cent.

(7) Asymmetric and mixed.
Percentage asymmetric axes in hyperopic eyes (yr. 1910) with normal vision.....40
Percentage of axes at or near 180° in asymmetric class...50
Mixed astigmatism, with v. = 20/40 or less—approximately 2 per cent of those with subnormal vision.

(8) Anisometropia.
Total percentage with unequal visual acuity in the two eyes due to errors of refraction, including both myopic and hyperopic types, amounting to 0.25 D. or more (no glasses worn) .....10 per cent.
Emmetropia.
Total *number* in whom no refractive error below 0.25 D could be demonstrated 18 or 20

Hyperopia and Myopia.

(10) Simple hyperopia and myopia (glasses not worn), 2.0 per cent.
Myopia of 5 D or more—a half-dozen cases.
Proportion of hyperopes to myopes among those who have subnormal vision: Hyperopes slightly in excess.

(11) Simple hyperopia and myopia (glasses worn) 3 per cent.
Myopia of low degree, 88 per cent.
Myopia of medium degree, 6 per cent.
Myopia of high degree, 12 per cent.
Cases with one eye myopic and one hyperopic.....30

Miscellaneous Data.

(12)
Percentage of 3326 students wearing glasses 27
Percentage wearing glasses constantly .....3 or 4
Percentage of 842 wearing glasses needing change of lenses 40
Number blind or practically so in one eye 15
Number totally blind in both eyes (year 1911-12)..... 6
Percentage with weak accommodation (no glasses worn) 4
Total per cent. with subnormal acuity 30

Percentage of students who have never consulted a specialist 40
Percentage with symptoms of eye strain (no glasses worn), approximately 25
Showing symptoms and glasses worn 22
Muscular imbalance of 5 degrees or more (no glasses worn) .....2 per cent
Nystagmus .....1 case
Diplopia .....Several

Women Students (360 examinations).

(13) 205
Vision normal both eyes, 70 per cent.
Hyperopic astigmatism, 88 per cent.
Myopic astigmatism.. 7 per cent.
Unclassified astigmatism, 3 per cent.

(14) 155* 43 per cent.
Hyperopic astigmatism, 40 per cent.
Myopic astigmatism..50 per cent.
Unclassified .....10 per cent

Miscellaneous Data.

(15)
Percentage of those not wearing glasses who showed symptoms of eye strain.....36 per cent.
Showing symptoms and glasses worn .....26 per cent
Number of serious cases of eye strain 28

Women who had never consulted a specialist .....40 per cent.
Asymmetric astigmatism, vision normal (no glasses), 42 per cent.
Anisometropia (no glasses), 12 per cent.
Simple hyperopia and myopia (no glasses)..... 2 per cent.

(16) Short Course Students (agricultural).† Total 1091.
Hyperopic astigmatism, 77 per cent.
Myopic astigmatism..17 per cent.
Unclassified astigmatism, 6 per cent.
Never examined by oculist, 50 per cent.

Wearing glasses.....12 per cent.
Glasses wrong.....40 per cent.
Showing symptoms (no glasses worn) .....13 per cent.
Marked anisometropia but no symptoms ..... 7 per cent.

†Mainly from rural districts, and attending courses for 12 weeks only.

son that, under the restrictions mentioned above, refraction work must necessarily be only qualitative. An attempt has been made in each case to determine the *manifest* myopia or hyperopia, and to locate as closely as possible the axes of astigmatism. The data given on this last point are presented as approximate figures only.

Discussion of some phases of the subject of eyestrain suggested by the above statistics.—The importance of visual defects in school life is now pretty generally recognized, though there is still a woeful lack of intelligent cooperation among parents, teachers, and physicians in dealing with children handicapped by malfunctioning eyes. This condition of affairs exists in spite of the fact that attention was long ago called to the prevalence of eye defects in school children by the papers of Erismann[1] and Conrad[2] (1874) in Europe, and by Vance[3] and Loring[4] (1877), Risley[5] (1878, 1881), and Randall[6] (1882) in this country. The results of these earlier writers have been abundantly confirmed by many ophthalmologists, both in America and abroad. That many children do not have their eyes examined at the critical time is well known.[7, 8, 9, 10] This neglect has been strikingly shown by our statistics, too, from which it appears that from 30 to 40 per cent. of the students have never consulted an oculist.* Among these young people have been found many with deplorable conditions of the eyes, conditions which are frequently due entirely to neglect or to ignorant treatment. This point will be considered later.

There are many phases of the subject of eyestrain suggested by the above tables, but only a few can be considered here. In the first place it should be stated that we have used the generally accepted standard of visual acuity, viz., the Snellen test letters at a distance of twenty feet. Those who could read the letters subtending an angle of 5 minutes were set down as having an angle of normal acuity, expressed as 20/20. If we had held the men up to the higher standard of 20/15, as some of the best oculists are now doing, there would have been found a much larger number with subnormal eyesight. With the standard used here 30 per cent. of all students had subnormal acuity in one or both eyes.

The next fact to be noted is the high percentage of hyperopic errors. The figures given are in fair accord with those of Posey and McKenzie[11] and with those of Zimmermann,[12] which, excepting the work of Derby[13] and Randall,[14] are about the only published statistics relating to eye defects among college students. The fact that the majority of eyes are hyperopic would seem to be too well known to deserve mention, but it is a fact which, after all, cannot be overemphasized, particularly in explaining to students and non-medical people generally the causes of eyestrain. When we consider that the hyperopic eye is relieved of work only a moment at a time during the whole of the waking period, and that when focussed upon near objects, as in reading or doing any close work, the strain put upon such an eye is tremendously increased, the wonder is that poor vision and resultant ill health are not more prevalent. It may be stated that in a large body of individuals as strong and healthy as the majority of American college students are, at least 10 per cent. will have subnormal sharpness of vision as a result of the strain induced by hyperopia and particularly by hyperopic astigmatism.

The importance of astigmatism was first clearly demonstrated by the epoch-making work of Donders,[15] and since his time volumes have been written upon the subject. It has been shown that the majority of eyes are astigmatic to a greater or less degree. Gould, basing his statement on the examination of 15,000 or more pairs of eyes, says that little or much of this form of ametropia is present in 99 per cent. of eyes. There is no doubt that astigmatism holds a commanding place as a pathogenetic factor.[16, 17, 18, 19, 20, 21] It is not the purpose of this paper to discuss this subject, however. It is permissible, though, to plead for a recognition of the importance of astigmatism as a cause of eyestrain and many forms of ill health, and to call attention to the fact that it is a condition which is often overlooked, because with the ordinary trial frame and lenses, and with some of the methods general employed, it is impossible to measure low refractive errors with any degree of accuracy. It should be appreciated, too, that often in normal visual acuteness, astigmatism, pernicious in almost every case, cannot be found, much less measured, without the use of drops or, in technical language, without cycloplegia. The inaccurate work done in ignorance of, and in open defiance of, such well-established facts is accountable for many failures to relieve distress caused by eyes laboring under the handicap of refractive errors.

In this connection may be mentioned other important facts. It is well to remember that hyperopic eyes, which are known to be so prone to set up disturbances of one sort and another, may, in the Leginning at least, cause no other result than gradually failing vision. In many instances we have noted marked reduction in acuity without the individual having suspected it. The explanation seems to be that the brain in such cases early fails to secure binocular vision, in that it neglects the impressions from one eye. In this way the individual may escape the sufferings of eyestrain, because of monocular vision, which, in the course of time, may result in permanent and severe injury to the neglected eye as a consequence of disuse. This means, of course, a great handicap; and there is the added danger of total blindness, or near approach to it, in case the better eye be injured by accident, of which there is no small risk among those students who work in chemical laboratories, machine shops, and the like. Generally, these eyes which are going out of function by reason of the disuse which the refractive error entails may be saved in these young people by proper glasses.

Another phase of the results of hyperopia, and of the astigmatism nearly always associated with it, is the matter of reflex disturbances met with in so called *nervous* individuals. These are persons with nervous systems of such a nature that persistent strain of any kind easily disturbs the equilibrium of the nervous organization, with the result that symptoms of the disturbance develop in one direction or another. Often these patients either fall into the hands of unscrupulous quacks who style themselves "specialists," or else wander into some sort of a sanatorium where a vague diagnosis is made and some such loosely used term as "neurasthenia" set down as the difficulty. They may be then treated by every therapeutic measure except accurately fitted glasses. In many instances a pair of scientific

*Gulick, in the MEDICAL RECORD, Vol. 70, page 12, says: "Not less than 30 per cent. of all children in our (New York City) elementary schools are suffering from ocular defects demanding correction, and not less than 17 per cent. have ocular defects so severe as to be a serious menace to their progress."

spectacles, properly worn, is all that is needed to restore the individual to health. We do not often meet with such cases in a body of college students, but we do encounter not a few students who have constitutions which can but poorly stand the pressure of a four-year course of study plus the extra strain which even a low grade of refractive error necessitates.

Allusion to this type usually calls to mind the poorly nourished, anemic person, more frequently a woman, who has difficulty in doing mental work and who often complains of being *nervous*. But these are not the only sufferers from eyestrain. There is another type altogether different, but not so frequently met with, represented by the big, healthy boy, whose strength and virility enable him to take part in such vigorous sports as football, hockey, etc., but whose life is often made miserable by severe headaches, and occasionally by insomnia, photophobia (hypersensitiveness to light), or indigestion. Most frequently the trouble first manifests itself as sleepiness on attempting to study, or as conjunctivitis or inflammation of the eyelids, etc. The symptoms are relieved to a large extent by strenuous exercise but often this fails to mitigate the discomfort which follows close work with the eyes. On examination, hyperopic astigmatism is usually found to be the cause of the difficulty, which disappears under proper treatment with glasses.

Myopia is also such a common defect, and people generally are so familiar with the prevalence of "near sight," that an additional word on the subject would seem quite unnecessary. The intention here is not to discuss myopia but to speak of the way in which it is, unfortunately, so frequently treated. Myopia may or may not be a very dangerous disease. Some oculists would say that it is always serious, inasmuch as it distinctly limits the field of vision. Certainly in progressive myopia we have a dangerous condition of the eye, and one which demands the most careful treatment. It is pitiful to see how some cases of near sight are handled, or even allowed to go unattended altogether. I remember one poor boy who came for examination about a month after entering college. He could not see a single letter on the test chart. It was quickly discovered that he had a myopia of about 2.50 D, with oblique axes of astigmatism. He had never had his eyes examined and was not aware that his vision was poor. He only knew that he did not see as well as some people. As the examination proceeded he became ill at ease, and when asked if the tests bothered him, he said that they made him feel "sick." The next moment he fell over in a faint. He was placed under the care of a good oculist, who had considerable trouble in carrying his examinations of the boy to completion at first, because of the nervous condition of the patient. Eventually the young man was enabled to continue his four-year course. How he could have done this without glasses is difficult to imagine. Many other instances of the neglect of eyes could be given, as could also many examples of the bungling attempts to relieve near sight. Many times have students come up for examination, which revealed that they had well advanced compound myopic astigmatism that had been entirely overlooked, or, what is worse, disregarded, by some one who had simply given plain concave lenses to improve vision.

At this point it should be stated that a fearful amount of botch work is done, both in the refraction of eyes and in the supplying and adjusting of glasses, with the result that there is almost as much *glass strain* as eyestrain.[22] We find refraction being done without cycloplegia when "drops" are absolutely essential for determining the true statical errors; patients are not required to return for confirmatory examinations and inspection of their glasses; they are not told the importance of keeping their glasses properly adjusted and cleaned; their eyelashes are allowed to rub against the lenses, and foolish notions about spectacles are permitted to interfere with the oculist's work. The most astonishing thing is the employment of incorrect test lenses, of which there must be an amazing number in the land, because it has been found that even the best optical firms have put out test cases, pronounced perfect, which in some instances have proved to contain many wrongly marked lenses, particularly among the cylinders. One such "perfect" set contained nearly 17 per cent. of incorrect cylinders.[23] In addition, the opticians who grind the lenses for the patient frequently do miserable work. They interchange the lenses, or reverse them, center them improperly, locate the axes wrongly, and adjust the frames badly. It is no wonder that people often fail to obtain relief, become discouraged, and eventually resort to almost anything in their despair.

Here a word may be said about the unfortunate and vicious legislative errors which have been made in this country. Our laws have made it possible for people to do refraction work without having any knowledge of the eye and its diseases, and particularly without the slightest idea of the close relation of ocular conditions to pathological states of other organs,[24] and thus it comes about that many persons, ignorant of the complexity of the eye, and of the skill and knowledge required to treat its diseases, generally due to refractive errors, place themselves in the hands of "eyesight specialists" and persons who make a great point about testing the eyes without the use of "poison drops." The result is that miserable refraction work is done and serious lesions of the eye are overlooked. Not infrequently these ocular disturbances are due to disease processes located primarily in other organs, and thus the diagnosis of dangerous maladies is delayed. Twenty-six states in this country encourage work to be done in this way by licensing people to practise "optometry"[25] [26] without a medical education and with no more experience than a few weeks' or months' training in elementary optics. And what is more to our shame, we are not yet rid of quacks who do not refract but who prey upon ignorant people by offering to cure for stated sums all sorts of serious ocular diseases by "magic eye treatment" of one kind and another. These are conditions which seem impossible when we think of how we pride ourselves on our twentieth century methods of education. They are serious matters which call for intelligent and careful consideration.

Allusion has already been made to the importance of astigmatism and of unequal visual acuity of the two eyes, or anisometropia, as this condition is technically called. The two subjects may well be given brief consideration together because the latter condition, which is much more common than usually supposed, is so frequently caused by the former. It is important to note that the percentage of eyes having unlike axes of corneal curvature is high. (We should remember that it is such eyes that most frequently cause trouble.) Further, it is interesting to observe that quite a number will have the axes exactly reversed in the two eyes, that is,

the planes of abnormal curvature will be at 90 and 180 degrees respectively, for example. All possible deviations from the vertical axis, 90, are found, and the percentage of odd axes is large. When we remember that, in addition to this, the amount of curvature defect in the two eyes may differ greatly, thus producing the condition called anisometropia, we can easily see how difficult it is, in many cases, to obtain binocular vision, and how great the corresponding strain upon the nervous and visual mechanisms may be. Dr. George M. Gould has emphasized the fact that an ametropic defect which throws the focus only 1/300 of an inch away from the point where it ought to be may interfere distinctly with the sharpness of vision. In the majority of ametropic eyes the misplacing of the image is more than 1/300 of an inch. Furthermore, because of the fact that the refractive power of the two eyes is generally not the same, the size, shape, and position of the two images are such that it is difficult, or impossible, to fuse the two impressions into one mental picture. It comes about that with this effort the coincident strain aggravates the defect, and sooner or later reflex functional disturbances arise, such as headache, nervousness, indigestion, and many other symptoms which presage the approach of ill health.

The author[27] just quoted, who has done so much in this country to emphasize the importance of exact correction of astigmatism and anisometropia, is of the opinion that these two conditions are the great causes of eyestrain, and secondarily of a large number of systemic diseases. The beginning of ill health is certainly often to be traced to reflex disturbances of ocular origin. One of the most interesting and valuable things that this writer has pointed out is the connection between right and left-handedness and right and left-eyedness, and the important practical bearing this relation may have in the treatment of visual defects.[28], [29] It is a subject incompletely investigated as yet, but it is doubtless of great significance. We have not appreciated fully the harm done to left-handed children in attempting to make them right handed, nor the damage that may follow when a left-eyed individual is compelled by an ocular defect to be right-eyed, or a right-eyed one to be left-eyed. In this connection it is important to recall that not every person with bad eyes has general symptoms. We have found many instances of astonishing degrees of ametropia, both of hyperopic and myopic varieties, with absolutely no symptoms of eyestrain. It may be said that it sometimes happens that no symptoms develop in these subjects until some unskilled person attempts to render the eyes emmetropic by glasses. It is clear that the danger of badly impaired vision in these insidious cases is great.

In completing this division of the subject brief allusion will be made to the relation of college work to increase of eye defects. We have not had opportunity here to follow up this subject, but we have undoubted proof that many eyes fail during the college course. It seems to be most noticeable here among architectural and engineering students, and is doubtless due to the great amount of drawing required of these men. One important factor in the production of failing eyes is poor artificial light and poor distribution of such light. There are thousands of students working many hours at night, and even many hours in daytime, with glaring electric lights shining directly into their faces. Lights are generally arranged in libraries, reading rooms, and laboratories without much reference to the comfort of those who must use them. There are great public and university libraries where hundreds of eyes are treated daily to the most unhygienic distribution of light imaginable. When shall we learn the injustice of this sort of thing?

Another cause of failing students' eyes is the use of skull caps, which furnish no protection from bright sunlight. To compel boys, especially those with sensitive retinas, to wear these caps in obedience to college customs is a vicious practice. More sensible caps could just as well serve to distinguish freshmen and sophomores, etc., and a vast amount of eye trouble would be prevented.

Eye-tests at various colleges and universities.—In the introduction it was stated that the thoroughness of the physical examinations at various institutions varies greatly. Bearing upon this point, I have collected statistics by sending a questionaire, with especial reference to eye examinations, to about 150 institutions of learning in this country. Replies were received from 105, and to those who were kind enough to answer the questions my thanks are due. Twenty-two of the institutions from which replies were received do not require eye examinations. Some of these institutions do not consider such work practical, others are indifferent, while a few have a genuine interest and enthusiasm in the work. Among those which do not require these examinations were three prominent schools of technology, two well known schools for women, and one great university, all having a large number of students. In most instances where the tests are made they are made by the physical director in charge, who is often not a physician. In only about a dozen institutions is an eye specialist engaged. Eighteen replies indicated that this sort of work was done with care and interest, to a degree that an effort had been made to get at important facts regarding the influence of eyestrain upon the college work and the health of the students. From the replies of these few schools it could be seen that the tests were being made carefully and that results were being recorded and studied. The writer was interested to know what estimate had been made elsewhere of the number of students needing glasses. In seventeen colleges and universities the estimates ranged from 10 to nearly 100 per cent., the latter figure being that from a government institution, where, it is stated, practically every student wears glasses before he finishes his course. The average of the percentages quoted is 34, which is probably not far from the truth. Taking the regularly enrolled men at this institution, the lowest estimate I can put upon the proportion whose eyes are defective enough to justify the wearing of glasses is 40 per cent. Among the women it will be higher by at least 5 per cent. In one well known college for women where careful examinations of the eyes are made, the physician in charge estimates that from 50 to 60 per cent. of the students wear glasses or need them.

From the facts given in this paper it may be seen that ocular defects must be an important factor in determining the efficiency of the work done by college students (witness the case cited). It is also apparent that we are sorely in need of means for examining more thoroughly the eyes of the public school children. Rough tests for myopia alone are all that are usually attempted, so that many cases of astigmatism and hyperopia are overlooked.

These are often the most serious cases. In

spite of the agitation which has been made, eye strain is a matter which has been too greatly neglected. There is no doubt that many a worthy student has been dropped in disgrace from his college when he might have completed his course with credit had his eyes permitted him to study as he desired to do. It is important to recognize, therefore, that eyestrain is not a fad and not simply a pet subject for eye specialists to harp about. Defective vision is a real condition afflicting most seriously the lives and careers of great numbers of people, and among our college students it is one of the most important factors which have to do with progress and success.

I wish to acknowledge my indebtedness to Drs. L. Coville, A. C. Durand, George M. Gould, J. S. Kirkendall, S. A. Mumford, and R. C. Wilson of Ithaca for assistance in collecting data for this paper. By the help of these gentlement the labor connected with the work has been made a pleasure.

THE PROBLEM OF VENEREAL PROPHYLAXIS.

By ROBERT A. BACHMANN, M.D.,

SURGEON, UNITED STATES NAVY; EXECUTIVE SURGEON UNITED STATES NAVAL HOSPITAL, NEWPORT, R. I.

In the matter of medical interest preventive medicine as contrasted to therapeutics has always been, more or less, the under dog. Metchnikoff's experiments proving that syphilis can be prevented by the application of a 30 per cent calomel ointment created quite a stir of attention, but nothing like the veritable storm of interest, even extending to the laity, which followed the announcement of Ehrlich's curative agent. Yet of the two, eventually, in the course of time the former will be adjudged the more valuable contribution to medical science and mankind. Where literally thousands of medical men rushed to the employment of salvarsan and a torrent of reports resulting from its worldwide use flowed in upon the medical press, only the most casual use was made of calomel ointment as a prophylactic and laboratory as well as practical corroboration was extremely meager.

In our army and navy, perhaps the greatest amount of interest was shown and attempts were made towards the practical application of Metchnikoff's discovery, but even here it cannot truly be said to have been the subject of much productive study, particularly systematic and scientific experimentation. The amount of work done in the two services, to put the question, of not only luetic but gonorrheal and chancroidal prevention on a sound basis, has been exceedingly conscientious as well as painstaking, but unfortunately the results are so lamentably at variance that at the present time the question—Does venereal prophylaxis prevent venereal diseases?—put to a dozen service medical officers will bring forth quite a diversity of opinion. The report of the Surgeon General of the Navy is what might be called only lukewarm in its comment:

"Venereal diseases continue to be the most potent factor of damage to the naval service. During the past year 138,083 sick days were caused by venereal disease alone. During the past year a system of prophylaxis against venereal disease has been carried out. The Bureau is of opinion that prophylaxis against venereal disease is of value. The decrease in the number of cases of syphilis is striking. It is believed that some form of prophylactic packet, which can be taken by the men and used immediately after exposure, will prove more effective. That there is not a more marked decrease is due to the more rigorous search for concealed cases; also a more widespread knowledge of the dangers of venereal infections has brought to the surface an increment of hitherto carefully concealed disease. To-day we

are obtaining a more accurate admission rate for venereal disease than the statistics of the Navy have hitherto shown."

That gonorrhea is not mentional as having suffered a "striking" decrease is significant, and as a matter of fact in the detailed report it holds its undisputed place at the head of the list of diseases. The admission rate for all venereal diseases for the last three years which comprise the era of prophylaxis, and the year 1906 for comparison, is as follows:

	Total Navy.			
	1906	1909	1910	1911
Personnel	41,313	52,913	57,172	58,340
	Gonorrhea			
Admissions	2,085	3,015	5,861	6,062
	Chancroid			
Admissions	537	665	1,573	1,968
	Syphilis			
Admissions	981	1,001	1,476	1,315

Now as the venereal propaganda was probably carried on more rigorously on board ship, where it could be done with greater efficiency, the statistics for the force afloat are also given:

	Force Afloat			
	1906	1909	1910	1911
Personnel	34,820	32,181	34,688	35,567
	Gonorrhea			
Admissions	1,641	2,054	3,956	3,906
	Chancroid			
Admissions	458	512	1,178	1,409
	Syphilis			
Admissions	710	564	829	849

From these figures it is rather difficult to see where the decrease in the prevalence of syphilis is accounted for, but this is evidently shown in special reports. The poor showing of the statistics is partly explained by the fact that the closer examinations of the men since prophylaxis was begun resulted in a much larger number of cases being detected and reported.

The Surgeon of the Army in his latest report makes this rather favorable statement: "The propaganda for the prevention of venereal diseases in the Army which was initiated by this office in January, 1909, has begun to show good results as demonstrated by the rates for 1910, as compared with the preceding year. These were as follows, for the whole army:

	Entire Army		Army in the United States Proper	
	1909 Per Cent.	1910 Per Cent.	1909 Per Cent.	1910 Per Cent.
Admissions per 1,000	196.99	174.95	177.46	155.51
Original admissions (cases)	169.61	154.91	151.35	137.98
Constantly non-effective rate	13.07	11.51	11.44	10.14

The admissions from each disease per 1,000 are as follows:

Gonorrhea and results:	
1910	102.44
1909	125.27
1908	123.50
1907	107.68
1906	105.21
1905	118.31
Chancroid:	
1910	26.42
1909	25.33
1908	28.20
1907	34.78
1906	26.41
1905	20.39
Syphilis:	
1910	26.65
1909	26.85
1908	23.15
1907	25.36
1906	27.28
1905	30.02
Total venereal:	
1910	155.51
1909	177.46
1908	174.84
1907	167.82
1906	158.91
1905	178.72

The campaign in the Army against the venereal evil was very active and particular attention was paid to the educational feature of it, in fact, some of the Army surgeons reported that this was the most important single factor. The Surgeon General's opinion, after detailed reports had been received from every station in the Army as to the value and results of the respective methods employed, is as follows: "It is plainly necessary for the War Department to take hold of the matter, and it is believed that sufficient experience has accumulated to accord a basis for a clear-cut, vigorous and successful policy. From these reports the following deductions may fairly be drawn: (1) Instruction of the men by lectures, printed circulars, and by medical officers and company commanders regarding the dangers of illicit and promiscuous sexual indulgence and the undoubted advantages of self-control and continence.

"Most of the reports bear testimony to the value of this instruction, and at some posts it is stated that a distinct improvement in the venereal record followed the delivery of lectures on these subjects. A few officers expressed skepticism of its value. One post surgeon in the United States and one commanding officer in the Philippines expressed the opinion that this is the only agency which should be used. It seems quite certain that this instruction is valuable directly in proportion to the earnestness devoted to it and the imagination and skill which is employed in making the instruction interesting and attractive.

"It is also clear that the efforts of the medical officers cannot accomplish much without the constant interest, moral support, and active assistance of the commanding officers and company officers. (2) Instruction in the employment of personal cleanliness and the use of disinfectant applications to prevent contagion by those men who will not be restrained by moral and prudential considerations from exposure to venereal diseases."

As I desire in this article to deal solely with the value of venereal prophylaxis as far as it concerns the efficiency of the present medical measures as distinct from educational, I have abstracted this last paragraph so that proper allowance may be made in studying the Army's figures, for the moral impression upon the men, its consequent increase of continence and resulting decrease of venereal admissions due entirely to that source. The above extracts may be assumed to represent the condensed opinion drawn from all the statistical reports sent in to the Army and Navy medical heads.

Venereal prophylaxis for the purpose of classification may be divided into two heads: the double method and the single method. Both can be applied immediately or later. The double method requires the application of two distinct substances to completely protect against the three diseases most common—gonorrhea, syphilis, and chancroid. The single method aims to accomplish the same result by the application of one medicament.

Various preparations and chemicals have been tried in the double method, but one is common to all—calomel ointment. The only variation in its use is in its strength. This ranges from 20 to 50 per cent. and is intended to protect against syphilis and chancroid. To prevent gonorrhea solutions of bichloride of mercury, silver nitrate, potassium permanganate, the organic silver salts, carbolic acid,

thymol, and eucalyptol have been used. The steps of application are about as follows: (1) Wash external genital organs thoroughly with Hg Cl_2 solution, 1-5000. (2) Inject into the urethra 4 centimeters of a solution of whatever chemical is thought best and retain this from 1 to 5 minutes. (3) Smear entire penis with a 25-50 per cent. calomel ointment, particularly about frenum.

This comprises the salient features of almost every one of the various double methods in use and is supposed to be efficient for as long as eight hours after exposure.

In the Army and Navy the double method is given the men after they return to the ship or barracks from shore liberty on the following morning. But attempts have been made to devise a means of immediate application. This has resulted in the getting up of various packages containing a syringe or dropper, an antiseptic solution, and calomel ointment. Collapsible tubes, being loaded on one end with protargol or argyrol solutions and on the other with calomel ointment, have been constructed, plain, or made to resemble a cartridge to disarm suspicion. The Army packet "K" consists at present of a protargol (20 per cent.) or argyrol (10 per cent.) solution, a medicine dropper or syringe and a vial of 30 per cent. calomel ointment. Different medical officers have modified this to suit individual ideas. The original packet, gotten up by Col. Raymond, contained no calomel ointment and was intended merely as prophylactic against "clap." So much for the double methods.

The single method consists of one medicament, usually an ointment, which protects against all venereal diseases. The bases of these various ointments are lard, lanoline, and vaseline, alone or in combination. Calomel is the principal ingredient and by some is considered a sufficient prophylactic against gonorrhea as well as chancroids and syphilis. Carbolic acid, thymol, argyrol, protargol, lysol, and trikresol have been used incorporated with the calomel to increase its preventive value against chancroid and gonorrhea. A collapsible tube of metal-paper, or celluloid is filled and is meant to be used as soon after exposure as possible. As with the double method no claim for efficiency longer than eight hours is made.

I think that at present throughout both services the double method has been generally adopted, this being particularly true of the Navy, where it is used almost exclusively. So the results obtained in the Army and Navy may, with approximate accuracy, be taken to represent the results of this one method. Two of the most recent reports, one from each service, are a good sample of how the double method is producing results. The first is by Holcomb and Cather,* and deals with 3,268 treatments on board the U. S. S. *Virginia;* the second is by Major Howard, U. S. A.† and gives his experience with 393 treatments at Jefferson Barracks, Missouri. The Naval prophylaxis consists of this procedure: "(1) Wash penis, head, shank, and under frenum with 1-5000 bichloride of mercury solution with a cotton sponge. (2) Pass water. Take urethral injection of 2 per cent. protargol solution and hold to count 60. (3) Rub 50 per cent. calomel ointment well into foreskin, head and shank of penis, with particular care about frenum. Either side of the frenum is the most frequent site of sores."

The results were:

Treatments, 3,268.

Gonorrhea	
With prophylactic	64 infections
Without prophylactic	50 infections
Sixteen cases took prophylactic within 10 hours.	
Chancroid	
With prophylactic	35 infections
Without prophylactic	27 infections
Nine cases took prophylactic within 10 hours.	
Syphilis	
With prophylactic	3 infections
Without prophylactic	12 infections

All cases infected after using prophylaxis were over the 10-hour interval. This is a rather good showing, particularly in syphilis. Major Howard's method was as follows: "(1) Wash external genital organs thoroughly with bichloride of mercury solution (1-5000). (2) Inject into urethra 4 c.c. argyrol solution (20 per cent.) using ordinary penis syringe. Solution to be held in urethra for full five minutes. (3) The entire penis will be smeared with calomel ointment (20 per cent.) and allowed to remain undisturbed. About 2 grams of ointment will be sufficient ordinarily. Especial care to be taken that the head of penis and foreskin are thoroughly covered." The report gives no comparative figures, but in 393 treatments covering two months, three cases of infection occurred. The total number of men exposed is not given, but 22 cases of venereal infection (not classified in report) occurred in men not taking any preventive.

From these reports it seems fair to conclude that prophylaxis is possible, but that it requires a great deal of attention on the part of the medical officers and that the double method itself must be very rigorously applied in order to be effective. Even then cases will occur. So it cannot be counted, at least in gonorrhea and chancroid, as a certain safeguard. In civil life where the strict routine and facility for controlling men are impossible it is impracticable. As for its immediate application it is so full of objections, such as difficulty of application, bulk of necessary packages, staining of clothes, etc., that we can confidently expect it never to be used.

The single method has had no extensive trials and reports on its efficiency are few. Colonel L. M. Maus, U. S. A., who is a warm advocate of the single method, made a favorable report* on the use of a special tube of his own invention, containing calomel ointment and 5 per cent thymol. He claims no cases of venereal disease occurred in troops assembled at Chicago for a military tournament, but he gives no figures. At Fort Benjamin Harrison, Colonel Maus gave his tube another test. I quote his report: "During my recent service at the Camp of Instruction, near Fort Benjamin Harrison, Indiana, I had another excellent opportunity to observe the effects of the prophylaxis. The regular troops, which remained here during the month, consisted of eleven companies Tenth Infantry, ten companies Twenty-sixth Infantry, eleven troops Sixth Cavalry, Company "A" Signal Corps, Company "I" Engineers and one-half Company "C" Hospital Corps. Each of these organizations was given a physical examination a few days previous to its arrival at camp to determine its fitness for field duty, and a list was submitted to my office of the men who were suffering from venereal diseases. All of the organizations were supplied with the prophylactic tubes shortly after arrival, and the men, in lectures by the regimental surgeons were instructed as to its use. I endeavored to have the tubes distributed to the

United States Naval Medical Bulletin, January, 1912.
†*The Military Surgeon,* December, 1911.
*The *Military Surgeon,* Dec., 1910.

men, but experienced no little trouble in so doing. Although the regimental surgeons, regimental commanders, and company officers were thoroughly satisfied as to the efficiency of the tube and its expediency, few of them took any interest whatever in the matter, so much so that quite a number of the men, who contracted venereal diseases during the encampment, informed me that they were not supplied with the tubes, and many of them that they had not heard of it, nothwithstanding the fact that each first sergeant was supplied with sufficient for each company, and was supposed to advise the men as to their use. In spite of the difficulties, however, nearly 3,000 tubes were issued during the month. A few days before breaking camp the command was given a second physical examination, this time in order to ascertain their fitness for the impending practice march, which had been ordered. A series of questions were asked each man examined regarding his sexual history during the month in connection with the tube, and, from the table compiled, the following facts were learned: (1) That 504 men had indulged in sexual intercourse during the encampment, who had used the tube after each contact. The number of contacts amounted to 1,301. Of these men two reported with gonorrhea, though one of them made glaring contradictions in his statements regarding the use of the tube, while the other man claimed that he had used the tube but did not understand it. (2) That 302 men had indulged during the encampment, who had not used the tube. The contacts of this class amounted to 763. As a result of these unprotected contacts one contracted syphilis, 26 gonorrhea, and 12 chancroids. In the first class of men, those who were protected, the percentage of infections per thousand amounted to ¼ of 1 per cent, while in the second class, the unprotected, the percentage amounted to 13 per cent. While I am not able to state it as a fact, I am morally satisfied that the three men who contracted the disease and claimed the use of the tube, had either not used it properly, or had failed to use it after the last contact during the seance in which they were infected."

In regard to syphilis, and perhaps chancroid, but at all events the former, the value of the single method needs no pointing out. Calomel ointment is the most potent half of the double method, as shown in almost every report. Applied immediately it can only be still more valuable. The best of evidence, namely, positive experimentation, is in its support. Metchnikoff and Roux demonstrated the action of fatty mercurial preparations as protectors against infection in monkeys, and incidentally also proved that non-fatty solutions were inert. Maisonneuve, as a result of their studies doubly inoculated himself with fresh virus and fresh virus from a luetic subject. Four monkeys were inoculated with virus on the same day, and one hour after inoculation Maisonneuve and one of the monkeys were rubbed on the site of the inoculation for five minutes with an ointment specially devised by Metchnikoff. The man, in the words of Metchnikoff, "notwithstanding the inoculation of a vastly larger quantity of active virus than would have been received in the ordinary way, remained absolutely free from any manifestations of syphilis." Metchnikoff therefore considers that this experiment shows that the application of calomel ointment within an hour of inoculation is preventive of infection both in the man and in the monkey. Experiments on monkeys showed that when the ointment was applied twenty hours after inoculation, the preventive action did not take place. G. N. Blech, at Michigan City, reports the case of a sergeant who exposed himself to a woman having a chancre on her right labium. He was protected within an hour by calomel ointment and escaped infection. Both direct and indirect evidence coincide with establishing the position of calomel ointment securely as a positive protection against syphilis. As the same ointment, reinforced by some other antiseptic, is designed by the advocates of the single method to protect also against gonorrhea, I shall bring some evidence to bear in support of this claim.

The indirect evidence is very scarce. Assistant Surgeon Reginald B. Henry, U. S. Navy, in his brief paper on "Calomel in Gonorrheal Prophylaxis," gives the result of a six-months' experience of the use of an ointment containing 50 grams of calomel, 80 c.c. of liquid petrolatum and 70 grams of lanolin among the men of the U. S. S. *Rainbow*, on the Asiatic station. During the period named, there were 529 admitted exposures, with four cases of gonorrhea. Of these four patients, one denied exposure and did not receive the treatment; two received treatment more than twelve hours after the exposure, so that only one possible failure of treatment remained, a percentage of .189. He finds the calomel cheap, efficacious, cleanly and non-irritating. The ordinary glass penis syringe was used for the injection of the ointment.

Direct evidence is furnished again by Dr. Blech. He infected with gonorrheal pus both eyes of a litter of pups, four in number and two weeks old. A few minutes later he injected 25 per cent. calomel and lard paste into the right eye of each pup, leaving the left eye unprotected as a control. In each case the protected eye escaped infection, while the unprotected eye became the seat of a severe attack of gonorrheal ophthalmia. This is a valuable contribution to the subject of prophylaxis and really affords more satisfying proof than any number of cases of indirect evidence. By indirect evidence I mean the adduction of proof through stating a given number of exposures with prophylactic treatment who have escaped infection. After all, an "exposure" does not mean an exposure to an active gonorrhea, and my own experience on the U. S. S. *St. Louis*, while sailing around South America, where the crew had great opportunity to contract venereal diseases, but actually escaped with less cases than the average ship reports now with prophylaxis, causes me to think that this fact has been overlooked altogether too regardlessly. One may refer back for instance to Surgeon Holcomb's report. He has 64 infections with prophylactic treatment and 50 without. Yet he states as his opinion elsewhere in the report that "with reference to the effectiveness of the treatment we would say that we feel reasonably certain that at least one-half of the men exposed present themselves for treatment. On this basis if 3,258 exposures took treatment we liberally estimate that 3,258 did not take treatment. This adds an element of uncertainty in reading these reports to anyone trying to arrive at some logical conclusion therefrom and the direct evidence of Metchnikoff, Roux, Maisonneuve and Blech affords a welcome element of stability and conclusiveness.

Having been convinced a long time of the worth of the single method I designed a tube and compounded an ointment last year which should overcome all the obstacles usually urged against the single method. In brief it consists of a collapsible

metal tube holding 6 grams of 33 per cent. calomel ointment reinforced by 1 per cent. trikresol. The main feature of the tube to which I ascribe its efficiency is a soft rubber nozzle 1.5 inches long which is inserted into the urethra and places the ointment well up beyond any possible area of infection and allows also a long time of contact with the ointment before it flows from the meatus. After a great many modifications the tube was brought to a satisfactory completion and the following experiments were made with it:

A patient having been confined in bed for a month with a fracture was given liberty. He reported gonorrheal infection a few days later. He had had no other liberty and named a certain inmate of a Newport brothel as the cause of his illness, and stated also that he had only exposed himself once very briefly and had taken the ordinary precautions such as washing, etc. This woman was easily identified from his description and slides made from the urethra, vagina, and cervix. All positive. Ten exposures were obtained. All of them escaped infection save one man, about the middle of the series, and his case presents some interesting features. A few days after his exposure it was reported to me that this man had taken a liking to the woman and repeatedly revisited her. The woman was interviewed, admitted his return engagements and stated he had not used tubes at these times. The woman was cautioned not to use douches during the time of the experiment and was again examined at the conclusion. All three slides as before were positive.

Medical Director Diehl, U.S.N., who has had a great deal of experience in venereal prophylaxis, being one of the first medical officers to observe its results while Fleet Surgeon of the Asiatic Fleet; P. A. Surgeon K. C. Melhorn, U.S.N., who instituted systematic prophylactic routine aboard the U. S. S. *Dixie,* and Assistant Surgeou A. H. Dodge, U.S.N., all watched this experiment, corroborated the slides, and were satisfied as to its completeness and accuracy. Considering the conveniences, practicability for the layman as well as for the army and navy, low cost, and efficiency, the tube method seems to be the ideal prophylactic and is well worthy of further study.

The question of a venereal disease is complicated and presents many aspects. As long as doctors are not the lawmakers, such legal measures as should be taken in controlling or eliminating prostitution, placing venereal diseases on the reportable list, giving freer education about sexual physiology and pathology, etc., will be matters of slow accomplishment. But why agitate for free dispensaries for venereal disease and direct other efforts along therapeutic lines? Why not class venereal infection with yellow fever, malaria, tuberculosis, typhoid fever, and plague and attack the evil at its inception? That is within every physician's power—the pioneer work has been done and justifies further effort. Why are medical men and medical societies so indifferent?

United States Naval Hospital, Newport, R. I.

Temperature Elevations in Children.—A. Wolff has found that a rise of temperature amounting to as much as 1.5° C. may occur in children, and may have no diagnostic significance. Moderate exercise, such as a short ten minute walk, and climbing the stairs a number of times, is sufficient to cause this rise of temperature. If such children are delicate or give a positive von Pirquet they are sometimes treated for tuberculosis, even though the disease may not be present.—*Zeitschrift für Kinderheilkunde.*

RECTAL ADMINISTRATION OF THE SALICYLATES IN THE INFLUENZA OF INFANCY.

By GEORGE WESLEY BEATTY, M.D.,

BROOKLYN, N. Y.

In a pediatric practice extending over a period of ten years, I have been called upon repeatedly to treat cases of influenza in young children, and during that time I have employed many agents noted for their efficacy in the treatment of this protean malady.

Quinine, in one or another of its forms, has justly held its place among this number and I believe we have no cause to alter our opinion of it. The salicylates are the next agent we have at our command and they held forth much promise, reinforcing our armamentarium very materially. Taken as a whole, the action of the salicylates is laudable, but owing to certain unpleasant symptoms following their use it becomes necessary to limit the amount of the dose, or to find a new form less irritating or a method of administration of the salicylates whereby their irritability is reduced to a minimum consistent with potentiality.

When salicylic acid or any of its derivatives is administered to adults, it must be greatly diluted—this is very well for the average adult, but even then its administration cannot be continued indefinitely. If this is the case with the adult, how much more are we handicapped when dealing with the stomach of an infant.

Sodium salicylate was introduced into the U. S. P. at the 1880 revision. This is a handy preparation, but there are those who prefer to make the salicylates themselves, and for these Dr. Hager (*New Remedies,* Nov., 1879) gave the following rule, whereby in the absence of the crystallized salicylate of sodium the salt might be prepared *in solution* by using the following proportions, in parts by weight of salicylic acid and sodium bicarbonate: "To make of sodium salicylate four parts by weight, take 3.3 parts of salicylic acid and 2.0 parts of sodium bicarbonate." This did nicely for the adult, but the infant stomach was still neglected. We had salicin—a neutral principle obtained from several species of *Salix* and *Populus.* This has, aside from its irritating effect upon the gastric mucosa, an objectionable feature in its intensely bitter taste. Salicin, when decomposed in the bowel, becomes salicylic acid—and in spite of its insolubility becomes rapidly absorbed. Statistics point to the fact that it is absorbed probably as salicylate of sodium; at least, this is the form in which it circulates in the blood. This occurs whether we administer salicin, salicylic acid, or sodium salicylate. Some believe that it exists in the blood as an albuminate, but of this there is no evidence nor is there any evidence that when sodium salicylate meets with carbon dioxide, salicylic acid is set free. Some of the salicylic acid of the sodium salt uniting with glycocol forms salicyluric acid and appears in the urine. The reaction which takes place is as follows: $HC_7H_5O_3 + C_2H_5NO_2$ (glycocol) = $HC_9H_8NO_4$ (salicyluric acid) + H_2O. The conversion of benzoic acid into hippuric acid by uniting with glycocol is analogous to this change occurring in ortho-oxybenzoic acid or salicylic acid.

Let us look now to another form of salicylate—methylsalicylate or synthetic salicylate. As far back as 1875 Professor Proctor discovered that salicylic

acid could be procured from oil of wintergreen (*Gaultheria procumbens*). Modern research has shown that methylsalicylate exists in many of the essential oils—oil of wintergreen contains 90 per cent. of this ether. Methylsalicylate or methylsalicylic acid when taken internally is broken up and eliminated as salicyluric acid. The bad effects reported following the use of the synthetic product were undoubtedly due to impurities in the preparation, such as metacresotic and orthocresotic acids.

Salicylic acid and all its derivatives are more or less irritating to the stomach, giving rise to pain, nausea, vomiting, etc., unless well diluted. An adult can stand large amounts of diluent, whereas a child, and especially an infant whose stomach capacity is small, cannot tolerate or accommodate the large amount of diluent necessary in the case of the salicylates. While sodium and lithium salicylates and salicin are less irritating they require dilution and this militates against their employment in young children. Another feature is salicylism—statistics show this to exist in 60 per cent. of the patients taking the salicylates.

The symptoms of salicylism are very like those of cinchonism. Both the natural and synthetic salicylates produce salicylism. Deafness, tinnitus aurium, headache (sometimes delirium), nausea, vomiting, a slow, low-tension pulse, flushed face, epistaxis, hematuria either alone or accompanying albuminuria, erythema, and urticaria are some of the untoward symptoms that may present from time to time. We learn of idiosyncrasies only after they develop, and they are not easily explained away to the apprehensive parents. Without going into detail concerning the symptomatology of influenza, with which we are all familiar, I would like to recapitulate some of the symptoms frequently found in very young infants—infants under six months old. Here we find peculiar features. The temperature here is often but slightly above normal, but the prostration is extreme—out of all proportion to the findings—pale face, sunken eyes, decided apathy, loss of appetite often to the point of refusing all alimentation. In some we find all the symptoms of acute pulmonary congestion, rapid breathing, cyanosis, feeble respiratory sounds, and yet auscultation reveals only feeble respiration.

Frequently we find undigested stools pointing to indigestion, also purpuric spots on thighs, chest, buttocks or back. These are usually few in number and resemble the rash of measles and when these occur with coryza, sneezing, suffused eyes, and slight photophobia and cough, they are often mistaken for measles, until subsequent developments reveal the true nature of the disease. In these little patients there seems to be a profound poisoning of the system which has produced such a severe shock that there is frequently not enough vitality to overcome it and the child rapidly succumbs. Frequently pleurisy develops. It is in these cases that I prefer some form of the salicylates; it is in these cases particularly that the salicylates are distinctly contraindicated, owing to their irritation of the gastric mucosa.

It is in these cases, especially with pleurisy, that I have good results with the salicylates. I am ever jealous of my patients' digestion, therefore I administer all or nearly all medication *per rectum*. In this medication I include the salicylates. Some years back in the treatment of dysentery and acute intestinal catarrh it was the custom to irrigate the large intestine with solutions of salicylic acid. This method was formerly employed for the removal of the *Oxyuris vermicularis*.

My treatment, aside from sustaining the heart, is to use quinine and methylene-citryl-salicylic acid (novaspirin); incorporating them into suppositories with oleum theobroma and introduce one such suppository into the rectum every six hours. First cleanse the bowel with a saline injection. The absorptive power of the rectum is practically 4 per cent., and as is the case in all rectal medication, the dose must be larger than it would be *per os*. I have never seen any untoward results from this method, aside from expulsion of the suppository; but if the nurse is instructed to compress one buttock against the other for a little time, the bowel will retain the suppository, which melts rapidly.

The patient almost invariably finds relief after half an hour and sinks into a quiet sleep, with usually a slight perspiration all over the body. Occasionally the urine will have a greenish tinge—this will be slight in infants and is undoubtedly due to either indican or pyrocatechin. My little patients have never presented hematuria, erythema around the anus, nor epistaxis with this method of administration, besides the stomach is kept uncontaminated and ready for food—the anorexia disappears usually in twenty-four hours, so that a milk diet may be utilized without fear and thus time and strength have been saved for the little sufferer.

THE MODERN MEDICAL CLINIC.

ITS PURPOSE AND ITS REQUIREMENTS.

By WM. HILLS SHELDON, M.D.,

NEW YORK.

CHIEF OF CLINIC, OUT-PATIENT DEPARTMENT AND INSTRUCTOR IN MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

Up to a few years ago the standard of work in a clinic was gauged by the quantity of patients treated and not by the quality of the treatment. We are now ready to acknowledge that this standard is wrong and that the modern clinic is not a place where the largest number of persons are treated with the maximum of speed and the minimum of attention, but an institution in which the most advanced results of medical science are applied to the diagnosis and treatment of disease. The time has past when patients can be shot in one door and out the next, receiving, as they pass through, a number, a ticket, and a prescription for compound cathartic pills or rhubarb and soda.

The conditions that exist in the dispensaries today, however, are too well known by those who have worked in them—and who of us has not—to need description here. The problem that now confronts the medical profession is, how are these conditions to be remedied?

The Purpose of the Modern Clinic.—Before any suggestion can be made with a view of solving this problem we must begin with a clear and definite appreciation of the purpose of the modern clinic. It exists for (1) the efficient diagnosis and treatment of disease; (2) the advancement of medical knowledge; (3) the prevention of disease by the instruction of patients in hygiene.

The system, or lack of system, now employed in the large majority of clinics renders the fulfilment of this purpose impossible, for careful diagnosis, research, and the instruction of patients takes time, a great deal of time, and time we have not got. Since, therefore, the present state of the dis-

pensaries is not—to put it politely—conducive to good work, this state will have to be changed, for careful, efficient, and scientific work must be done.

In considering the requirements necessary to each of the three above-mentioned branches of work, I think it will be found that this broad development of the medical clinics will result in benefit, not only to the sick poor, but to the doctors working among them.

1. *The Efficient Diagnosis and Treatment of Disease.*—The two great essentials for efficient diagnosis and treatment are: (a) A sufficient number of doctors to work, (b) the scientific facilities to work with. (a) There will, of course, be differences of opinion as to what constitutes a "sufficient" number of doctors, but I think a conservative estimate should allow one doctor to every six patients in a two-hour clinic. This would enable the physician to spend half an hour each on the examinations of three new patients, and ten minutes each on the treatment of three old patients. For a fair-sized clinic averaging forty-eight patients, a daily staff of eight men would be required, each man working a full two hours a day, and not one hour or one hour and a half. (b) Equal in importance to the necessity of an adequate staff is an up-to-date equipment, for the time has passed when a doctor can be expected to do good work with a persuasive manner, a fountain pen, and a prescription blank.

A Well-Equipped Laboratory is absolutely necessary if a clinic is to be scientifically run, and it should be connected with the department, and be in charge of a skilled laboratory worker and his assistants. Routine examinations of urine for all new patients can thus be made on the spot, and this very often enables the physician to complete his diagnosis at the patient's first visit. Sputum and blood examinations, Wassermann and Widal reactions, and all the modern tests can be made in suitable cases, and such data are essential, if a careful and thorough diagnosis is to be made. Moreover, by situating the laboratory in connection with the medical clinic the clinicians have the advantage of consulting frequently with the laboratory men, and each has the opportunity of correlating the laboratory diagnoses with the physical signs of the patient.

Scientific Instruments of Precision have become of such value to the diagnostician that no clinic can be considered properly equipped without them. Blood pressure cannot be accurately gauged except by a sphygmomanometer, and the sphygmocardiagraph not merely frequently reveals abnormal conditions of the heart which could not be determined by the stethoscope, but also enables the physician to analyze cardiac irregularities.

The venous pressure apparatus offers great possibilities for research, as do other instruments of this kind, and it is not the least part of their value that they direct the attention of the physician to the newer work upon the heart.

An X-Ray Department is a most important adjunct to a medical clinic. It is not merely indispensable in the diagnosis of obscure conditions and an aid to research, but it is also a great stimulus to careful diagnosis, as the *x*-ray photograph shows up any errors in a most impartial and indisputable manner. The advantages of the *x*-ray are too well known to need discussion and I merely wish to emphasize the desirability of employing this apparatus as a diagnostic factor in the medical clinics.

A Mechanico-Hydrotherapeutic Equipment is of the utmost importance, for this method of treatment is of the greatest benefit in various diseases. This is particularly true of chronic joint conditions, as numbers of these patients become cripples simply for lack of this treatment. Some nervous cases, which have been drugged for years without improvement, are greatly helped by hydrotherapy and mechanicotherapy, while in circulatory and kidney diseases its value is well known. Diseases of metabolism and chronic intoxications are more often relieved by this method than by any other.

We are far behind the European clinics in regard to this valuable therapeutic measure. In a city like New York, where there is so much wealth, there should be little difficulty in obtaining the funds necessary to its installation in certain of our dispensaries. I venture to say, moreover, that if this equipment were more generally installed the osteopaths and others would soon be forced out of business. Doctors have shaken public confidence by promiscuous drugging, and they must restore it by the intelligent use of other therapeutic agents.

An Accurate System of Filing and Indexing Histories is an important point of equipment, for all the time spent upon patients in the dispensary is absolutely wasted unless careful histories are taken and filed in such a manner as to be easily referred to. These histories are of vital importance during the treatment of the case, and when it terminates they are of great value from the standpoints of research and statistics. It is, therefore, necessary that they should not merely be carefully preserved, but be easy of access.

I should like to suggest to those who may be contemplating new indexing systems, that the vertical filing system is infinitely superior to the horizontal system, and gives twice the space at one-eighth the cost. The using of large single-sheet histories still further economizes space; these should be filed by number and not by name, as they are then more quickly referred to.

The system of nomenclature employed by the Bellevue and Allied Hospitals is excellent, and the result of an exhaustive study into the subject on the part of the authorities. A uniform system of indexing and nomenclature among all clinics is greatly to be desired, and would put an end to one of the most insidious temptations that beset a chief of clinic, *i.e.* to improve whatever system happens to exist in his dispensary.

2. *The Advancement of Medical Knowledge.*—It is of the utmost importance to encourage research in the medical clinic, for not only does the physician have the broadening influence of the work itself, but it also does away with the deadly monotony of clinic routine. In the medical clinic of Cornell University we have put in practice a system of division and specialization of work that has proved satisfactory in every way. At the present time one physician is making a specialty of gastrointestinal diseases and doing the necessary analyses, assisted by the laboratory; another is making a study of occupational diseases: a third has taken up diseases of the thyroid; a fourth is interested in *x*-ray diagnosis, cooperating with the *x*-ray department, and studying also medicosurgical conditions: and another is working on diseases of the heart. In this way each physician studies those cases in which he is particularly interested and the special knowledge that he acquires is of considerable value in consultations over unusual cases.

3. *Prevention of Disease by the Instruction of Patients in Hygiene.*—The highest ideal of the medical profession is not simply to treat and cure disease, but to prevent disease, and it is the duty of the medical clinic, just as it is the duty of the private physician, to teach patients how to avoid sickness by the observation of hygienic rules. A great responsibility rests upon the medical clinic in this respect, inasmuch as the patients with which it deals are the poor and uneducated, who know nothing of the necessity for proper ventilation, food, exercises, and cleanliness, or their relation to the laws of health. What is more, a large proportion of the diseases from which dispensary patients suffer are brought about, in the beginning, by ignorance of these laws; and I believe that in the future much may be accomplished by persistent education in hygiene.

In a previous article* I have dealt with the advantages, to both patient and physician, of printed forms of instructions. By this method much time is saved and better results secured than when the directions are given verbally. In the Cornell Medical Clinic we have six leaflets, entitled "Rules for General Health," "What to do for Constipation," "Directions for Persons with Heart Disease," "Directions for Persons with Kidney Disease," "Instructions for Persons with Chronic Joint Disease," "Instructions for Persons Exposed to Industrial Diseases, Especially Lead." We intend to add to these leaflets from time to time. We have also given out a dietary containing a list of cheap, nourishing foods, with instructions how to cook them properly.

The first obstacle to be overcome in the betterment of clinic conditions is the difficulty of systematizing and coordinating the city dispensaries. It has been suggested that the city be divided into districts, each district having its own clinic, and that the patients in each district be required to attend the district clinic. This would be a great economy in time and labor, for both the patient and the doctor. Under the present system patients wander from clinic to clinic, just as they please, consuming the attention of the doctors, various boxes of pills, and many car fares. It is a most unprofitable arrangement for all concerned, and the sooner it is changed the better. If, moreover, a social service nurse were attached to each clinic to investigate the circumstances of all new patients, the element of grafting patients could be largely done away with, and the number of persons attending public clinics greatly diminished. This would relieve the overcrowding of the dispensaries and enable the physicians to give proper attention to those who really need free medical attention.

The difficulty of obtaining the right kind of men to work in the clinics is equally grave. While it is comparatively easy to get men for the eye and ear, nose and throat, genitourinary, and other specialities, there is undoubtedly an increasing difficulty in getting men for the medical clinics. A good many physicians are anxious to perfect themselves in one or other of the specialties, for these offer greater opportunities in private practice as regards both professional and financial success.

There are several causes that are partly responsible for this shortage in the medical dispensaries. One is, that during the past few years there have been more clinics established and fewer students graduated from medical schools. Then again, the laboratories and the Department of Health offer salaried positions which are very acceptable to the young physician.

Lastly, and perhaps most important of all, the clinics themselves are responsible, for they have not kept pace with the precepts of medical education or modern medical thought.

The staff of a clinic is largely made up of young men, newly graduated from medical schools and hospitals. These men, during their years of training, have been imbued with the idea of oding good, scientific work, so that eventually they may contribute something to their profession. These men will not work in the clinics as they are run today, for the clinics offer them nothing; certainly not the opportunity to do good work; still less a salary, and the prospect of advancement is too remote to be a great attraction.

These are the physicians we need, and it is obvious that inducements must be held out to them to attract them to our clinics. Every facility for diagnosis in the way of equipment must be given them, and every effort should be made by encouraging research to make the clinic work interesting and of scientific value.

Apart from these considerations I think it will be found necessary to attach a salary, even if small, to dispensary positions. The expense of medical education is so great, and the cost of living so undeniably high, that the young physician must necessarily favor those positions which pay, rather than those which do not.

THE PHYSICAL SIGNS OF PULMONARY TUBERCULOSIS CAUSED BY NASAL STENOSIS.

By MARY E. LAPHAM, M.D.,

HIGHLANDS, N. C.

HIGHLANDS CAMP SANATORIUM,

When we find a lack of development in the upper part of the chest because of insufficient expansion of the chest wall and lack of inspiratory force, we urge with great earnestness the necessity for the expansion and development of the lung by means of vigorous breathing. This flat, sunken chest appeals to us at once, and we do not underestimate the importance of correcting the fault by deep breathing. But there are other dangers due to an insufficient transmission of atmospheric force through the nose that are not so apparent, and are far more easily overlooked because the outward signs are not there to suggest the hidden condition. The chest wall is well developed, the breathing is deep, and yet hidden away above the first rib is a spot where the force of the entering air is not sufficient to keep all the air passages open, and so some of them collapse, and an atelectatic area is formed which will sooner or later be invaded by connective tissue and converted into the collapse induration due to stenosis of the nasal air passages.

The collapse of a few air passages in the apex does not cause any physical manifestations. There is no irritation, no cough, absolutely nothing to call attention to the danger, but gradually, as the induration increases, complications occur; dust and bacteria settle out from the blood and lymph currents transporting them, and eventually an active inflammation produces the physical signs of a chronic

fibroid bronchitis that may well be mistaken for tuberculosis.

Until within a year I did not know that such a bronchitis in an apex could be due simply to nasal stenosis. I did not know that loss of strength and weight and appetite, that a bad cough and expectoration, that breathlessness and palpitation on exercise, that night sweats and hemoptysis could all be caused merely by obstructing the free passage of air through the nose. Nor did I know that simply for the same reason the apex could be markedly shrunken, Kronig's field narrowed, and nearly the whole of the upper lobe become dull and infiltrated. During the last year I made two mistakes in diagnosis in consequence of this ignorance.

The first was that of a young woman who had been exposed to tuberculosis for some time in taking care of a relative. She had lost weight and strength. There was a slight cough but no expectoration. The right apex was shrunken; the percussion note was higher; there were wet râles; the breath sounds were suppressed and the expansion of the Alveoli uneven—precisely like an initial stage of tuberculosis when the nodules are still isolated and dry, before the development of collateral edemas in the perituberculous areas. Taking the history and physical signs and the patient's condition altogether, I made the diagnosis of an initial tuberculosis in the apex. There was also a chronic follicular pharyngitis. The vault was stuffed up with a thickened oral lymphatic ring, and the posterior turbinate was enlarged. After these faults were corrected by operation the structural changes in the lungs disappeared and I had to admit that my diagnosis was wrong.

The second case was that of a young girl of thirteen, pale, not strong, not eating well, with daily temperature of over 99°. The family were afraid of tuberculosis, and wanted to be assured that there was no cause for anxiety. There were wet and dry râles over the right apex, and a good deal of irritation down to the second space in front and to the spine of the scapula behind. There were enlarged tonsils, adenoids, and a thickened posterior turbinate. After these were removed the physical signs in the lungs became normal, and the patient improved in every way.

Blumel[1] and Richter[2] have reported cases of structural changes in the apex, associated with such typical tuberculous manifestations that it seemed as if nothing but tuberculosis could be the cause. The patients were weak, there were dyspnea and palpitation on exertion, breast pains, cough, expectoration, night sweats, and hemoptysis. The physical signs were: Prominence of mouth breathing conditions, hypertrophy of lymphatic oral ring, enormous nasal hypertrophy, and no nose breathing. The right lung was affected much oftener than the left, both in children and adults. There was shrinkage of the right apex with a narrowing of Kronig's field, marked dullness and altered breath sounds, from simply slight suppression and uneven expansion, up to catarrhal characteristics, and even bronchophony. The lung was affected down to the second rib in front and spine of the scapula behind. The physical signs were clearly those of a chronic fibroid interstitial bronchitis, absolutely typical of tuberculosis, but which disappeared by the correction of the nasal faults and establishment of free breathing through the nose.

Why should nasal obstruction cause atelectatic areas in the apex that go on to collapse induration and chronic fibroid bronchitis? Why is it that only the apex is affected in this way? It is because it is more difficult to fill the air passages and alveoli in the apex than it is those of the rest of the lung. It is harder to get air up into the apex and to keep the apical air passages open, because there are no muscles of inspiration and no chest wall to expand and pull the alveoli open. How do we get air into and out of the lungs? We enlarge the thoracic cavity by pulling out the chest wall, and because the lung is not large enough to fill the thoracic cavity it stretches as it follows the chest wall, and in stretching the walls of the alveoli are pulled apart. Then the pressure of the atmosphere upon the column of air, reaching from the nose to the alveoli, forces it to follow these retreating walls; the column of air sinks until the alveolar walls remain stationary, and then inspiration is over. Inspiration is the removal of the support to the base of the column of air reaching from the alveoli to the nose by pulling the alveolar walls upon which it rests away from it, so that the pressure of the atmosphere transmitted through the nose forces the air column to instantaneously follow the retreating walls of the alveoli. When the distention of the alveoli is accomplished the chest wall collapses, the elastic fibers in the alveoli contract, and the column of air is driven up again. The length and diameter of the column of air moved in respiration are out of all proportion to the base upon which it rests. It is so trifling and insignificant that it may be said to be all base. The diameter is only that of the trachea, while the base consists of millions of alveoli, which, if spread out, would cover approximately 100 square feet. Small wonder that the slightest change in the base affects the column intensely, and that, *per contra,* the base is only with difficulty affected through the column.

Inspiration is the pulling open of alveolar sacs because the lung is not large enough to fill the thorax, and when it follows the chest wall it has to stretch, and so the walls of the alveoli are pulled open. Those alveoli that are most pulled upon by the expansion of the chest wall will be best filled by the descending column of air, and this occurs where the motion of the chest wall is greatest, where the thoracic cavity is most enlarged, and where the lung has to stretch most, which is in direct proportion to the distance from the first rib. The thorax hangs from the first rib, which is nearly rigid. From the second rib down to the lowest ones the expansion and the enlargement of the thoracic cavity progressively increase, so that we have more distension of the alveoli and better inspiration the farther away we get from the first rib. More than this, the distention of the alveoli is greatest upon the surface of the lung immediately beneath the pleura. The pull of the chest wall is not felt very deeply within the lung, so that those alveoli lying next the pleura breathe most, and those within the central portions of the lung hardly breathe at all. The functional activity of the alveoli depends upon their walls being pulled open, and to accomplish this we have the powerful muscles of inspiration and the expansion of the chest wall. But what mechanism is there above the first rib? There is no way to pull these apical alveoli open and they have to depend upon changes of pressure transmitted from below. The inspiratory pressure filling the apical alveoli is secondary and indirect. When the air column is driven downward it forces some air on up into the apex, but with nothing like

the force that it presses into the air passages farther down. If the force of atmospheric pressure is destroyed by preventing its free transmission through the nose, the transmitted pressure may not be great enough to distend equally all the passages in the apex, and if any one of them fail to obtain their due supply of air those that are better filled will press against them, and, lacking sustaining support from within, they will be crushed together and atelectatic areas develop. At first this is not permanent, but repetition gradually establishes it, and from atelectasis some lobules go on to collapse induration. The stasis of blood and lymph encourages an overgrowth of connective tissue in these collapsed areas, and when dust and bacteria are deposited out from the slowed currents of the blood and lymph circulation there results a chronic fibroid bronchitis or a streptococcic softening or other structural changes corresponding to the irritant. Above all, we have a good preparation for the growth of tubercle bacilli.

Why do these collapse indurations only occur at the apex of the lung? Because this is where atmospheric pressure is least able to keep the air passages open. It would seem as if breathing through the mouth would transmit atmospheric pressure thoroughly enough to keep these alveoli open. Collapsed areas occur in the apex even with pronounced mouth breathing. The demand for oxygen sufficient for respiration is supplied, but the pressure is not adequately transmitted to the apex by mouth breathing, because it disturbs the fine mechanism upon which perfect respiration depends. There is no doubt of the rapid entrance of air. It is quite possible that it is too rapid and that the alveoli farther down, where the pull of the chest wall is greatest, are filled relatively long before the apical alveoli can get their share. General alveolar pressure being equalized over the greater portion of the lung, expiration follows before the inspiratory wave has reached the apical alveoli. In order for the inspiratory wave to have sufficient time to reach these apical alveoli, we must have the prolonged action of nose breathing, which has the same effect upon the distribution of air pressure to these alveoli that the diaphragm of a camera has to the diffusion of light rays. A small aperture enables the light rays to slowly and adequately affect the circumference, while a large aperture affects the center long before the periphery. Besides the lack of cleansing, warming, and moistening the air, mouth breathing must have this sin laid to its charge: It fails to expand the apical alveoli and to maintain the force of the blood and lymph circulation through the paravertebral region.

The relation of nasal obstruction to asthma is fully admitted. Is there an equally intimate connection between nasal obstruction and tuberculosis of the apex? Finding some form of nasal obstruction so frequently in my cases of tuberculosis, I have come to believe that this is so. Nasal obstruction disturbs the mechanism of respiration in the weakest part of the lung, *i. e.* the right apex, and causes symptoms and physical signs that are absolutely typical of tuberculosis. It may be that the establishing of good, free breathing through the nose may not only alter the conditions threatening the physical and mental development of the patient, but also lessen his chances for a tuberculous invasion.

In all cases of tuberculosis of the apex associated with nasal obstruction we should remember that there is danger of diagnosing the chronic fibroid bronchitis of collapse induration as tuberculous, and, therefore, reserve our decision until the effect of correcting the nasal faults is observed.

Since a comparatively slight hindrance to the transmission of atmospheric pressure through the nose may cause the formation of atelectatic areas in the apex that go on to collapse induration and chronic fibroid bronchitis, we should be more careful than ever to see that our patients have good, free breathing through the nose.

THE ICE-BAG AND APPENDICITIS.

By A. M. FAUNTLEROY, M.D.,

SURGEON, U. S. NAVY.

To advance an idea at this late date with reference to the treatment of appendicitis seems rather presumptuous in view of the enormous amount of literature on the subject, and the only excuse the writer has to offer is that there seems to be at least one point in the varied pathology of this organ which has been overlooked or for lack of certain data not recorded. The idea to be advanced is in the nature of a warning with reference to the more or less common use of the ice-bag as a part of the preoperative treatment in this condition and is the result of observations in a series of seventy cases which have come to operation during my surgical service on the U. S. Hospital Ship *Solace*.

In this series sixty per cent. of the cases were either gangrenous, or about to perforate, or there was pus formation. The ice-bag had been used in about fifty per cent. of all the cases, as noted in the health records of the patients, prior to being sent to the hospital ship for operation. In each one of these cases a careful white count (sometimes two) was made immediately upon admission and recorded in the health record. The cases were as promptly operated upon as their condition seemed to indicate and in cases where the ice-bag had been used, sometimes one day and sometimes two days prior to operation, there was a noticeable lack of effort on the part of nature to wall off from the rest of the abdominal cavity, the appendix which was frequently very much congested, gangrenous, or perforated. It was also noted in these ice-bag cases that there was a suprisingly low white count when one took into consideration the condition found in the abdomen at the time of operation. From eight to eleven thousand white cells was the rule in these ice-bag cases when one would be justified in saying that the pathological condition warranted a constitutional reaction of between twenty and thirty thousand leucocytes or even higher. On the other hand, in those cases in which the hot water bag or morphine had been used prior to operation (the ice-bag not being used at all) the white count corresponded to what one would expect from the condition encountered in the abdomen and, in the type of cases mentioned, there was also a distinct walling off of the acutely inflamed or gangrenous appendix from the general peritoneal cavity, showing that Nature had been able to use successfully all of her forces in localizing the process.

In view of these observations, I am forced to conclude that the ice-bag is distinctly harmful in appendicitis and should never be used. Undoubtedly the ice-bag has been used with the idea of relieving pain and spasm, but if in relieving these symptoms

it does harm it should be discarded in favor of some other remedy which is equally efficient along these lines and which is not detrimental to the patient.

There is no surgeon of any experience who is not convinced of the soundness of the principle which underlies Bier's hyperemic treatment, and this being accepted there is every reason to discard the ice-bag since the latter brings about a condition directly opposite to what we strive to accomplish in carrying out this principle in the treatment of inflammation involving the peritoneum. While undoubtedly in most cases it relieves pain it also decreases the hyperemia for the time being, thereby driving away, so to speak, the protecting leucocytes from that quadrant of the abdomen and eventually bringing about a condition of stasis and consequent devitalization which is doubtless analogous to the action of cold in connection with the condition commonly known as frostbite. The pain of appendicitis is due to the local engorgement and consequent stretching of the peritoneum in the neighborhood of the appendix and its relief by the application of cold is very probably due to the numbness or lack of sensation on the part of the peritoneum brought about in practically the same manner as the familiar numbness of a frostbitten ear or toe. It would also seem that the application of cold and consequent numbing of the peritoneum so deludes Nature that she does not call out the reserve leucocytes and hence one valuable point of information is suppressed, namely, leucocytosis, the degree of which in connection with other symptoms is a valuable indication as to whether or not immediate operation is necessary.

The writer is well aware of the difference of opinion which exists among medical and surgical men with reference to the use of the ice-bag in appendicitis and it is not claimed that the opinion expressed in this paper is original, but as far as can be learned by conversing with a number of prominent surgeons, who are also authors of textbooks, these particular points with reference to the leucocytes and the findings at operation have never been brought out and it is at the urgent suggestion of these surgeons that this paper is submitted with the hope that at least a discussion of the subject will be precipitated and others will be led to record and publish their findings.

The above series were all young and active men between the ages of twenty and forty. A very small percentage (5 per cent.) had a history of previous attacks. The invariable rule in the Navy is to operate in every case in which a diagnosis is made, so that practically recurrent attacks can be ruled out except in the few who gave a history of trouble in the right iliac region prior to enlistment. They were also young men whose general health had been excellent prior to admission and in whom there was every reason to think that there would have been a sharp systemic reaction in case of any serious trouble with the appendix.

U.S.S. "Solace."

The Effects of Depancreatization.—H. Labbé studied the effects on the general nutrition of the dog of partial resection of the pancreas. When subjected to conditions giving rise to an acid intoxication the animal is capable of eliminating an excess of ammonia, like the normal dog. This would show that the functional activity of the liver is, if at all, but slightly affected. The production of urea is the same as in the normal animal. These results are not entirely in accord with those of histological examination, which show a certain degree of degeneration of the hepatic cells, which is probably the result of previous intoxications.—*Revue de Médecine.*

Neuropathies and Psychopathies of Genital Origin.—L. M. Bossi advocates the gynecological examination of every woman who comes before a court of law for the commission of a crime, whether it be stealing, or a crime of violence, or attempted suicide, and that it be ascertained whether she has any genital anomaly before she is tried or condemned. In the same way every woman who becomes insane should go through an examination for the presence of utero-ovarian anomalies before she is sent to an insane asylum. If she has genital troubles she should be treated and will often recover entirely. It is not the serious lesions like cancer, fibroma, and peritonitis that cause alienation, but the slow, insidious infections, and the displacements that render the life of the victim insupportable, and make her unable to do her work or mix with society, that by the presence of a slow infection and the symptoms of autointoxication affect the nervous system. The author cites cases known to him and treated by him in which kleptomania occurred only at the menstrual period, which with its added nervous irritability made a criminal of the woman. Many violent crimes are the result of such a condition eventuating in a sudden access of insanity from some slight excitement occurring at a neuropathic period. It is the duty of physicians to recognize these facts and endeavor to educate the public so that these persons should receive proper gynecological treatment, instead of being incarcerated in prison or committed to asylums. Under proper treatment many a hysteric, epileptic, or insane woman will recover from both her uterine and her mental disease.—*Revue Mensuelle de Gynécologie, d'Obstetrique, et de Pédiatrie.*

Genital Hypernephromata in Women.—H. Alamartine and G. Maurizot state that abberrant suprarenal capsules are found in connection with the tissues of the broad ligaments in women, as well as in the neighborhood of the pancreas and liver; they are seldom seen in men. The suprarenals are derived from the celomic epithelium of the internal face of the mesonephron. Masses of cells become separated and form separate accessory glands. Overgrowths of the accessory suprarenal glands are rare in women; they are peculiar in that they are enucleable, but show malignancy. They cannot be diagnosticated before the abdomen is opened, but when they come into view may be immediately recognized by their characteristic structure. They are seen either in young immature girls, or in women between fifty and sixty years of age. The cytological characteristics of the cells are marked, and especially the contents of fat in them. Obesity accompanies their presence. Circulatory disturbances result from hypersecretion and the production of suprarenal hormones, causing slowing of the pulse and hypertension.—*Revue de Gynécologie et de Chirurgie Abdominale.*

The Incidence of Streptococci in Urine.—H. W. Crowe states that two distinct cocci occur in the urine with comparative frequency, and both are probably streptococci. When certain symptoms suggesting slight toxemia are associated with chronic rheumatism, streptococci may usually be found in the urine. Vaccine treatment in such cases is remarkably beneficial. In acute rheumatism the organisms described are usually absent from the urine. The isolation of the organisms and the preparation of vaccines are greatly facilitated by the use of neutral red egg medium. In general, if one is justified in drawing any conclusions from the small number of cases studied by the author, streptococci are met with in the urine more frequently in slight ailments than in severe diseases. The latter believes he has made out a case for systematic cultural examination of urine, whether attention is directed thither by symptoms or not, with the likelihood of its proving a fruitful field, both from the pathological and the therapeutic standpoint. —*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, August 3, 1912.

THE MEDICAL REVOLUTION IN GREAT BRITAIN.

THE passage of the National Insurance Bill of Great Britain is a matter of supreme importance to the medical profession. The crisis has been reached and the medical practitioners have decided they will not be bound down by the provisions of the act. At a special plenary session of the British Medical Association at Liverpool on July 23 the resolution passed a few days before to the effect that the members of the association refuse to act under the present conditions of the bill was passed with enthusiasm. Thus the British government is placed in the position of being unable to give the chief benefits promised to the people by the act. Sir James Barr, the president of the association for 1912, who is notorious for his outspokenness, went so far as to characterize the insurance act as "the most gigantic fraud ever perpetrated on a confiding public since the days of the South Sea Bubble."

The scheme has been severely criticised from various standpoints, but the proposed treatment of the medical profession is that which has caused the present deadlock. A short sketch therefore of its main features, so far as the profession is concerned, will not be out of place. To anyone who is familiar with or even fairly cognizant of the conditions of the poor in the big cities of Great Britain a plan which seems likely to better their lot will find universal favor. The scheme of national insurance has been called great, and from many points of view it undoubtedly is great. In the first instance, when Mr. Lloyd George suggested the scheme his suggestion was received with acclamation by men of all shades of politics. Some indeed have decried the plan, urging that it tends to pauperize the working classes and to perpetuate the unfit rather than to bring about lasting improvement to the race. On the whole, however, men of all creeds and political opinions in Great Britain hailed with fervor any method which was calculated to amend or ameliorate the existing state of affairs. Consequently the British statesman appeared to open his new campaign under most favorable auspices and to have the opportunity of deeply engraving his name on the scroll of fame as one of the greatest benefactors of his race. How, then, has it happened that instead of this glorious consummation the act, after its provisions were known, became a source of contention and dispute almost without parallel in the history of English legislation? We will not attempt to deal with other parts of the bill open to criticism, but will confine our comments to those which intimately affect the medical profession. The benefits of the Insurance Act from a medical point of view are: (1) Medical treatment with drugs, etc., throughout life; (2) pay during incapacity from sickness; (3) a maternity allowance; (4) some provision for the treatment of tuberculosis, principally by means of sanatoriums. The essential of the scheme then may be said to be an adequate command of competent medical skill, necessarily implying for its successful carrying out the earnest cooperation of the medical profession. What were the inducements offered to the medical practitioners in order to secure this cooperation? The pay offered for the services of the profession was $1 a year per head with an allowance of 50 cents a year for drugs, etc. The scale of remuneration is said to be somewhat higher than that in club practice in Great Britain, but this extra remuneration is altogether outweighed by the loss of private practice which must follow as the result of the extension of medical benefits from 6,500,000, the number now served by contract, to 14,750,000, many of whom are well to do and able to afford a fair fee for medical services. Again, the reduction of income is intensified by the fact that, unlike present club practice, which is confined to selected lives and healthy persons, those benefiting by the act will comprise all sorts and conditions of men, women, and children and will accordingly bring about a totally different kind of practice. Not only, however, does the British practitioner face inadequate pay and a probable considerable money loss, but what he resents most bitterly, the act places him in the hands of the "approved societies." He has already had such experience of the ways of these societies as to dread his position if the provisions of the bill are rigidly enforced.

The British Medical Association has laid the following demands before the Chancellor of the Exchequer: (1) An income limit of $10 a week; that is, a person receiving beyond that amount would not be eligible for the benefits under the act. (2) Free choice of doctor by patient. (3) Medical and maternity benefits to be administered by State insurance committees and not by friendly societies. (4) Two dollars and ten cents to be the minimum capitation fee, not including extras and medicine. To all of these apparently just demands Lloyd George has given a *non possumus* and has moreover treated the medical men throughout the negotiations with much contumely and has endeavored to prejudice the profession with the community as standing in the way of the public weal, swayed solely by selfish interests. Earning a capitation fee of $1 a year with 50 cents added for drugs, etc., in order to gain the barest of livings the medical man must do an amount of work which is out of all proportion to the recompense. Judging from the results of the Insurance Act of Germany, the average earnings of a medical man under the British Act would be between $1,000 and $1,500 a year. When it is considered that the medical education of the physician is the longest, hardest, and most costly of any technical

education, that his position as a physician entails great responsibility, the assurance of Mr. Lloyd George in expecting him to become absolutely the servant of the public at a remuneration of less than $1,500 a year is nothing less than remarkable. In Great Britain this is the more glaring seeing that the British House of Commons has voted recently to each of its members the sum of $2,000 a year for services which require no special education to perform adequately and which are light and to a great extent perfunctory.

Contract practice is everywhere unsatisfactory not only to the physician but to the general public. A laborer is worthy of his hire, and if he be not recompensed for his services properly he does not, nay he cannot, fulfill his duties as they should be fulfilled, and therefore in the long run if the doctor be starved and compelled to lose his self respect every one concerned must suffer. It would appear that the British chancellor has promised more than he can accomplish and the sooner he is brought to an understanding that such is the case the better will it be for the country. One thing is certain, that the outcome of the struggle between the British government and the medical profession must profoundly affect medicine in all its branches for good or evil, and this being so the matter closely concerns the medical profession of this country. It is, in short, a valuable object lesson for medical men in all parts of the world. A notable feature of the situation is the sane, temperate, and dignified manner in which the question has been discussed by the leading medical journals of Great Britain—in striking contrast to the heated appeals to party and class prejudice made by politicians responsible for the introduction of the measure and by the lay journals obviously interested in substantiating and popularizing their statements. The principle embodied in the scheme is excellent, but the manner in which the principle is being exploited to the detriment of a self-sacrificing body of men and to the ultimate hurt of the community at large savors of low political ideals. The progress of the battle will be watched with absorbing interest by physicians here and the hope may be expressed that even yet a compromise will be reached honorable to those directly interested and for the good of the people at large.

SALVARSAN IN THE TREATMENT OF RABIES.

The season of supposed maximal prevalence of hydrophobia has arrived. In spite of municipal ordinances providing for the muzzling of dogs, there are reported almost daily in the public press instances of individuals bitten by rabid animals. A certain proportion of these individuals who will not take early advantage of the Pasteur treatment will eventually enter the hospitals as hopeless cases of fully developed hydrophobia. Possibly in these cases a gleam of hope still exists, if the results recently obtained by R. Tonin (*Il Policlinico,* July 14, 1912) in the treatment of a case of hydrophobia by means of salvarsan should be verified by other observers.

The case was one of a girl thirteen years of age, treated at the Antirabic Institute of Cairo, Egypt. She was brought to the Institute twelve days after she had been bitten by a dog presumably rabid. The usual course of treatment by means of inoculations was carried out for a period of fourteen days, at the end of which time the child began to suffer from general malaise, headache, and slight fever. These symptoms grew more intense and were supplemented by a difficulty in swallowing liquids and solids. At this time, four weeks after having been bitten, the child was admitted to the Italian Hospital. On examination she presented a picture of great anxiety with dyspnea and laryngopharyngeal spasm. This was aggravated by the sight of water or by spraying the latter upon the patient's skin, or even by lightly blowing upon her face (aerophobia). There were also intense headache, general hyperesthesia, and a heightened temperature. The outcome was considered hopeless and death was expected in from four to six days. Tonin, basing his action upon the supposed protozoal origin of rabies, and upon the parasitotropic property of salvarsan, administered this drug to the child intravenously in a dose of 30 centigrams. There then occurred the usual symptoms resulting from the injection of salvarsan —a rise of temperature, an acceleration of pulse, and repeated vomiting. At the same time the symptoms of hydrophobia began to improve, so that by the following morning there was little difficulty in swallowing, and the anxiety and hyperesthesia had markedly diminished. The improvement was so striking that the author began to question the original diagnosis, when on the twenty-seventh day the child gave evidence of a paresis of the lower limbs, and formication in both feet. There then developed the symptoms of an ascending myelitis: paresis of the muscles of the back and of the upper part of the arms; involvement of the bulbar centers as manifested by rapidity of pulse and respiration and by frequent vomiting; intense occipital headache; abducent paralysis; and rigidity of the neck muscles. In spite of these grave manifestations of meningomyelitis and encephalitis, the patient recovered completely, after a course of treatment including the administration of digitalis, iodides, camphor, and ascending doses of strychnine, and the employment of hot baths.

The author presents a rigid analysis of the above case, disposing in turn of all the alternative theories that might be advanced to account for the extraordinary recovery. He excludes the possibility of a nervous or false hydrophobia. The child had never manifested any nervous symptoms, there was no disturbance of sensation, and there were no hysterogenic zones. Moreover, in false hydrophobia the symptoms are largely and almost exclusively psychic and do not include these associated with an ascending myelitis. In explanation of the immediate improvement following the use of salvarsan, and then the secondary onset of paralytic symptoms, the author suggests that the drug in destroying the microorganisms had set free their endotoxins, which were then responsible for these later lesions. He

cites the remote analogy of the postdiphtheritic paralysis that may occur even after the effective administration of antitoxin. Another possibility that suggested itself was that the original antirabic inoculations might have been responsible for the symptoms of rabies that developed in the patient. In an extensive experience with this method of treatment the author had seen two instances of transient irritation of the spinal cord following the inoculations, but never any evidences of hydrophobia.

The history of the above case naturally does not prove that salvarsan is a specific in rabies, but the results obtained were sufficiently impressive to justify the use of this drug in cases that have not submitted to the preliminary antirabic inoculations, and in which a lethal outcome is almost certain. At any rate there is some basis for the hope that rabies may be included among the diseases, such as syphilis, relapsing fever, and frambœsia, in which the parasitotropic virtues of salvarsan or of its derivatives have been amply demonstrated.

HEMOPHILIA.

At the present time the subject of heredity is one that fills with hope the mind of the amateur eugenist. Those who know most concerning the matter are, perhaps, the most sceptical as to the practicability of the application of its principles to the human race in the prevention of disease. On the other hand, those who possess a superficial knowledge of the question discourse glibly of the regeneration of mankind mentally and physically by judicious breeding. A moot point, and one which requires a great deal of further investigation before an agreement is reached, is with regard to the diseases which are inherited. Until this question is settled far more definitely than it is now, it is somewhat idle to attempt to state who shall mate and who shall not mate. There are some diseases which obviously should be a bar to marriage, but these are few.

In hemophilia inheritance is certainly a very potent factor, indeed, all-important. The disease is rare, but from the standpoint of heredity extremely interesting. As Sir Thomas Oliver writes in *The Practitioner* for June, 1912, the disease is an affection of the middle layer of the blastoderm, but how the mesodermal defect originates and what it really consists of it is impossible to say. The pathology of hemophilia has yet to be written. It is generally allowed that in the thin and fragile condition of the walls of small blood-vessels and in the altered composition and impaired coagulating power of the blood is to be found the explanation of many cases of persistent hemorrhage. Since it is from the leucocytes of the blood that the ferment comes which encourages clotting, it is useful to know that in male "bleeders" as well as in their mothers and sisters, there is a deficiency of leucocytes, especially of the polymorphonuclear type. It is then to the subnormal number of leucocytes that must be attributed, in the first instance, the defective coagulability of the blood. As Oliver points out, however, it is not that the blood does not coagulate, but that notwithstanding the presence of a clot, blood still oozes from underneath it as if the tissues were not supplying their quota of fibrous ferment, or as if the clot itself did not undergo those physical changes in association with adhesion of the walls of the blood-vessels which lead to blocking of the same. Experimental evidence seems to show that in an altered constitution of the blood is to be found the explanation of the immediate bleedings in hemophilia.

The main interest of this uncommon affection lies in the fact that it is inherited and in the manner of its transmission. Women of a bleeding stock transmit the hemorrhagic diathesis mainly to male offspring. Males exhibit but do not transmit the tendency to bleed. Plate, in the work, "Hérédité Gynephore," shows how the influence of sex determines whether life shall be brought to a premature close or not by antenatal conditions. Plate includes in "gynephorous heredity" a mode of transmission characterized by the transmission of disease by females apparently normal to half of their male descendants, while in the female offspring the disease is concealed in a latent form. In this, as in hemophilia, the females seemingly healthy play the rôle of transmitters. Certain animal experiments, the results of which were reported by Federley to the Fourth Congress of Genetics, would seem to prove that there is in the organism of the female some inherent specific sexual disposition which not only confers protection but also the power of rendering latent within herself certain genetic tendencies which become actualities in her male descendants. There is, however, much yet to be learned regarding hemophilia, and from the point of view of heredity the subject may be recommended to eugenists and mendelists as a fitting one to investigate.

Zoster.

The occasional occurrence of this disease in epidemic form, the constitutional disturbances accompanying it, the associated glandular enlargement, and the degenerative changes that have been demonstrated in the posterior spinal ganglia, all point to an infectious agent as being responsible for the affection. Confirmatory evidence is afforded by the fact that rarely does an individual suffer from a second attack. Furthermore the study of atypical forms of the distribution of the eruption indicates the operation of some general agent. J. Minet and J. Leclercq (*Revue de Médecine*, February 10 and March 10, 1912) made a special study of these atypical cases, which vary all the way from a zoster without any eruption to one in which the eruption is widely distributed. There are the abortive forms in which the eruption does not go beyond the vesiculopapular stage; the forms with a double, bifurcated, or trifurcated eruption; the instances of bilateral, symmetrical eruptions; and the double nonsymmetrical, the multiples, and the aberrant forms. Many dermatologists of large clinical experience have never seen a case of bilateral symmetrical zoster, nevertheless forty-three cases have been reported in the literature. The eruption may be simultaneously symmetrical, or after a normal evolution for several days on one side, it may appear in exactly the same form on the other side and at the same level of the body. It may consti-

tute a veritable belt about the body; this occurs more frequently on the face and on the thorax. Contrary to the views of the older writers, the prognosis in these cases is no worse than in simple zoster, although the duration of the disease may be longer and the general reaction may be more intense. Only one fatal case has been reported, and in this instance the lethal outcome was the result of a secondary infection.

Stigmata of Degeneration and Radiography.

That radiography should be able to extend our knowledge of degenerative stigmata is readily apparent when we bear in mind how largely these concern the osseous system and teeth. Radiograms should readily bring out asymmetries. Naturally stigmata of degeneracy may be associated with actual disease of the bones, as in rachitis or syphilis. At a session last spring of the Society of German Physicians of Prague (*Berliner klinische Wochenschrift,* June 24) Lissau demonstrated an instructive example. Two brothers aged 7 and 9 had no lower and but two upper incisors. The latter were pointed like those of carnivora. The *x*-ray showed that the missing teeth had been retained. Had they grown, however, the denture would have been defective. The rays also showed that the bones, especially those of the skull, were abnormally thin, senile—a sure mark of degeneracy. The skin was thin with no fatty content, the hair lusterless. The whole picture seemed to be one of a vice of first conformation which had involved by preference all the ectodermal organs.

News of the Week.

Plague on the Increase.—New cases of plague have been reported in both Porto Rico and Cuba, and the efforts of the health authorities are being directed toward cleaning up the towns and exterminating the rats. Assistant Surgeon Creel, in charge at Porto Rico, has been given an additional surgeon and three inspectors to be used in examining freight to be shipped to the United States. Large forces of rat poisoners and rat catchers are at work and 500 rats are being examined daily. No cases of the disease have appeared in Trinidad and vessels leaving Port-of-Spain are given clean bills of health. The United States Treasury Department has ordered that vessels from ports in South America and the West Indies, Africa, Russia, China, India, and the Pacific Islands, while lying in United States ports shall have all lines or hawsers leading to wharves or shore protected by rat guards and that all gang planks shall be raised at night unless men be placed near by to destroy escaping rats.

Plague Rats Found in American Ports.—After hundreds of negative examinations of rats had been made during the past few weeks one rat carrying plague bacilli was found in New Orleans on July 27 and one in Philadelphia on July 29. The city health officers of both places have issued statements to the effect that while there is no cause for alarm the fight against the rats will be continued until they are exterminated.

Lister Memorial.—Plans are being made in London for the establishment of a memorial to the late Lord Lister. The memorial will probably take the form of a monument in Westminster Abbey, and the foundation of an international prize in surgery or of fellowships in research in scientific centers in England and abroad.

Decrease in German Births.—The perilous decrease in the birth rate in Germany will, it is said, shortly be the subject of official inquiry. The government announces that the fall in the rate has been almost constant from 1876 when it was 42.6 per 1,000 to 1911 when it was 30.7. It is stated that the falling off is much less marked in Roman Catholic than in Protestant communities.

Medical Society of the Missouri Valley.—The twenty-fifth annual meeting of this society will be held in the city of its birth, Council Bluffs, Iowa, on September 5 and 6, 1912, under the presidency of Dr. J. M. Bell of St. Joseph. Those desiring to present papers should send their titles to the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo., before August 1 with abstracts not later than August 10.

Wood Alcohol Poisonings.—The New Jersey State Board of Health has just brought to a successful finish a campaign for the enforcement of the pure food law, in which hundreds of gallons of liquors and cordials having wood alcohol for their base have been seized and dumped into the sewers. The product was found in the possession of Italian tradesmen and the crusade was started by the Italian Consul in New York, who appeared before the Department of Agriculture with five of his countrymen who had been poisoned by the fluid, two being blind and the three others in a serious condition. Investigation showed that a wine blending and importing company in New York had been handling the stuff and that it had been largely used in the Italian colonies at weddings and funerals.

Dr. Bevan Resigns.—The resignation of Dr. Charles F. Bevan as dean of the College of Physicians and Surgeons of Baltimore, which office he had held for ten years, was announced recently. Dr. William F. Lockwood, professor of the principles and practice of medicine, has been elected to succeed Dr. Bevan.

Dr. Josephus Arthur Wright of Towson, Md., has been appointed superintendent of the Sydenham Hospital of Baltimore, succeeding Dr. Robert A. Warner.

Iowa State Boards.—Dr. Albert De Bey of Orange City, Iowa, has been elected president of the Iowa State Board of Health, and Dr. T. U. McManus, president of the State Board of Medical Examiners. Dr. G. H. Summer of Des Moines has been elected secretary.

To Visit Hospitals Abroad.—Dr. George O'Hanlon, superintendent of Bellevue and Allied Hospitals, New York, accompanied by Dr. M. S. Gregory, resident alienist at Bellevue Hospital, sailed from New York on July 24 with the intention of inspecting the hospitals in Europe.

Prof. Ludwig Pick.—The American students of Professor Pick, of whom there are about six hundred, will tender him a complimentary dinner on Saturday evening, November 16, on the occasion of his visit to New York. Particulars may be obtained from Dr. Charles Goodman, 969 Madison avenue, New York. Professor Pick, as has already been announced, will deliver the Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons early in November.

Dr. A. M. Fernandez-Ybarra, formerly of New York City, has been appointed physician and surgeon of the Spanish Club Sanatorium of Tampa, Fla.

Dr. Clifton A. Gardner of the New York Post-Graduate Hospital is reported missing. He left the

hospital on the afternoon of July 23 to visit an outpatient and has not been seen since. He did not visit the patient. Dr. Gardner was 27 years old, a graduate of the University of Pennsylvania in 1911, and had been ten months on the hospital staff.

Hospital Cost.—That the high cost of living generally is affecting the cost of hospital maintenance is the complaint of the superintendent of the Johns Hopkins Hospital, Baltimore, in his report just issued. The cost of caring for patients is greater at the Johns Hopkins Hospital than elsewhere, and the expenditures during twenty-two years have amounted to more than $5,000,000, while the total gross receipts have been only about $2,000,000. Sixty per cent. of the hospital's patients have been in the wards under free treatment.

Brownsville Hospital.—The Brownsville and East New York Hospital has purchased as a site for a Jewish hospital fifteen lots in Brownsville on Avenue C between Rockaway Parkway and East Ninety-eighth street. Plans are being prepared for the new building which it is estimated will cost $100,000.

Promoting Public Health.—The New York State Department of Health is now seeking the cooperation of the labor unions in its work of promoting public health by education and has appointed a special representative to facilitate the carrying out of the campaign by visiting labor organizations and enlisting their aid in preventing communicable diseases and in taking steps to avoid the special diseases and accidents incident to the occupation of their members. Arrangements will be made for special meetings of the labor organizations to be addressed by lecturers of the State Department of Health.

Irish Wreck Sanatorium.—At Lucan, a village near Dublin, Ireland, a sanatorium for the treatment of tuberculosis, which was in course of construction, was demolished on July 22 by the villagers who had already displayed much hostility to the scheme of making Lucan a health resort. A mob armed with ropes and pickaxes first tore the roof off and then threw the walls down, leaving nothing but débris. The sanatorium was being erected under the auspices of the Women's National Health Association.

Fewer Fatal Accidents.—During the month of June fifteen persons were killed in accidents on the street railways of New York City, as against twenty-four in June, 1911. The number of serious accidents also decreased from 270 to 206. There was, however, an increase in the total number of accidents reported from 5,997 in June, 1911, to 6,342 in June of this year, while the total number of persons injured, though not seriously, increased from 3,827 to 4,184.

Infant Mortality Rate Lowered.—For the week ending July 20 there were 328 deaths of infants under one year of age in New York City, as compared to 348 in the same week of last year. Since the first of the year the number of infant deaths totals 479 less than for the corresponding period of 1911.

Infantile Paralysis.—Twenty-eight cases of infantile paralysis with three deaths had been reported to the Health Department of Buffalo, N. Y., up to July 24.

Somewhat Doubtful.—According to the records of the church at Tuxpan, Mexico, José Calvario, who died there recently, had reached the age of 185 years.

School on Hospital Roof.—The New York Board of Education has authorized the establishment of a class for tuberculous children on the roof of the Long Island College Hospital, Brooklyn. This is the first instance in which a public school class has been joined to a hospital, although a similar class has been conducted by the Department of Education on the roof of the Vanderbilt Clinic, New York, for several years. There are also various other roof classes on school buildings throughout the city and additional ones will be opened this fall.

Gifts to Charities.—By the will of the late Mrs. Ellen Collings of New York the Lincoln Hospital in this city receives a bequest of $1,000. The sum of $5,000 is also left to the American Endowment Fund of the Lebanon Hospital for the Insane in Syria, Asia.

The late James E. Childs of New York left $50,000 to the Thrall Hospital at Middletown, Conn., subject to a life interest of the testator's wife.

Eugenics Congress.—The first international congress on eugenics opened in London on July 24, with over four hundred delegates in attendance. Among the delegates from the United States were Dr. Charles B. Davenport, director of the station for experimental evolution at Cold Spring Harbor, N. Y.; Dr. Raymond Pearl of the Maine Experimental Station, Dr. D. F. Weeks of the New Jersey State College, and Dr. G. Smith of the University of Minnesota, all of whom presented papers to the congress.

Doctors Protest Against the Insurance Act.—The new National Insurance Act which recently became effective in England has met with much opposition, and particularly from the members of the medical profession, who have refused to agree to the provisions made in it for fees for medical attendance. The Chancellor has offered six shillings for medical attendance under the act for each insured person per annum, and the physicians have made a demand for eight shillings sixpence as a minimum. This being refused the delegates to the British Medical Association in session in Liverpool on July 20 voted to break off all negotiations with the Chancellor, who may thus be compelled to start a State medical service. In fact a scheme for a public medical service organized and controlled by physicians was outlined at a meeting of the medical association and was received with favor.

Dentists in the Army.—The Surgeon General of the Army announces that examinations for the appointment of acting dental surgeons will be held at various places throughout the country on Monday, October 7, 1912. Applicants must be between 21 and 27 years of age, citizens of the United States, graduates of authorized dental schools, and of good moral character and habits. Acting dental surgeons are employed under a three years contract at the rate of $150 per month. After this period they may be promoted to the grade of dental surgeon with the rank of first lieutenant and with the pay and allowances pertaining to that rank. Application blanks and full information concerning these examinations can be procured by addressing the "Surgeon General, United States Army, Washington, D. C." There is a large number of vacancies to be filled.

Michigan Accepts Leper.—After considerable discussion the Michigan State Board of Health has consented to receive the leprosy patient who recently escaped from Bay City in that State, where he had been kept under observation, and was recaptured in Buffalo. The New York State Board of Health was not willing to assume the responsibility of his

care. The incident has led to a discussion of the advisability of federal control of leprosy in the United States.

Medical Society Elections.—The Austin Flint Cedar Valley Medical Society in annual session at Waterloo, Iowa, on July 11 elected the following officers for the ensuing year: *President,* Dr. Elmer E. Dunkelberg, Waterloo, Iowa; *Vice-President,* Dr. Willis F. Cobb, Lyle, Minn.; *Secretary,* Dr. C. F. Starr, Mason City, Iowa; *Treasurer,* Dr. Will L. Hearst, Cedar Falls, Iowa.

The annual meeting of the Iowa and Illinois Central District Medical Association was held in Davenport, Iowa, on July 11, the following officers being elected: *President,* Dr. Wilson W. Adams, Atkinson, Ill.; *Vice-President,* Dr. Peter A. Bendixen, Davenport, Iowa; *Secretary,* Dr. Lawrence W. Littig, Davenport, Iowa; *Treasurer,* Dr. Frank H. First, Rock Island, Ill.

At the annual meeting of the Washington State Medical Association held in Tacoma on July 7, it was decided to hold the next meeting in Spokane on June 7, 1913, and the following officers were elected for the coming year: *President,* Dr. Howard R. Keylor, Walla Walla; *Vice-President,* Dr. A. MacRae Smith, Bellingham; *Secretary,* Dr. Frank Paine Witter, Spokane; *Treasurer,* Dr. W. T. Thomas, Tacoma.

The Oregon State Medical Society held its annual meeting in Portland and on July 6 elected the following officers: *President,* Dr. Robert Ellis Ringo, Pendelton; *Vice-Presidents,* Dr. James S. Moore, Portland; Dr. Fred D. Stricker, Grant's Pass, and Dr. R. W. Stearns, Medford; *Treasurer,* Dr. Katherine C. Manion, Portland; *Secretary,* Dr. M. B. Marcellus, Portland.

The Brazos County (Texas) Medical Society at its first annual meeting held in Bryan on July 6 organized with the election of the following officers: *President,* Dr. George F. Lee, Wellborn; *Vice-President,* Dr. William B. Cline; *Secretary and Treasurer,* Dr. Robert Jasper Hunnicut, Bryan.

Obituary Notes.—Dr. James A. Exton of New York and Arlington, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1866, a veteran of the Civil War, a member of the New Jersey State and Hudson County Medical Societies, the American Medical Association, the American Public Health Association, the Jersey City and Newark Practitioners' Club, and the New Jersey Sanitary Association, one of the founders and president of the Hudson County Medical Milk Commission, and consulting physician to St. James' Hospital, Newark, died at his home in Arlington from paralysis on July 25, aged 68 years.

Dr. Maurice H. Richardson of Boston died at his home in that city on July 31. He was born at Athol, Mass., December 31, 1851. He was graduated from Harvard in arts in 1873 and in medicine in 1877 and began the practise of medicine in Boston after the usual hospital service. He was appointed demonstrator of anatomy at Harvard in 1882 and since 1907 was Moseley professor of surgery. He was surgeon to the General Massachusetts Hospital and a member of the American Surgical Association, the Massachusetts State Medical Society, and the American Medical Association.

Dr. Harry C. Largeman of Philadelphia, a graduate of the Medico-Chirurgical College of Philadelphia in 1899, and a member of the Pennsylvania State and Philadelphia County Medical Societies, died at his home, on July 15, aged 39 years.

Correspondence.

THE LARGE INCISION AND THE REASON FOR IT.

To the Editor of the Medical Record:

Sir:—The able article under the above caption in the Medical Record for July 20, by Dr. Percy A. Perkins, is in line with a number of articles upon the same subject recently. There is much to be said in favor of the large incision, and Dr. Perkins very concisely and correctly points this out. I would call attention to the reason for my activity some years ago in directing the attention of surgeons to the desirability of the short incision. At that time unnecessarily large incisions were made in appendicitis work, of the sort in which "the more thorough the operation, the more quickly the patient died." The results of employing the short incision led to the inception of the principles of the fourth era in surgery, in which the patient is to be left as far as possible under the care of his own protective factors. His protecting organs are not to be disabled by the shock of any really unnecessary operative technique. Lately, however, we have come into much new knowledge concerning Lane's kink, Jackson's membrane, and bile tract adhesions, which were often overlooked when the short incision was employed in abdominal work.

The last word to be said on the subject is perhaps this: Make as perfect a diagnosis as possible before doing any operating at all. In many cases it will then be possible for the surgeon to allow his patient to escape a serious attack of surgery. The surgeon may have the satisfaction of employing considerable technical skill in making a small incision—in selected cases. Through the short incision in appendicitis work, he may often discover the presence of a Lane kink, or of Jackson's membrane, and then proceed to make as large an incision as the case requires.

At the time when I drew the attention of the profession to the advantages of short incisions, the subject seemed to be timely, and to serve a purpose. At the present time it may still serve a purpose, but in connection with newer knowledge, and with newer care in making correct diagnosis before attempting any sort of abdominal operation.

Robert T. Morris, M.D.

616 Madison Avenue, New York.

A NEW CONSCIENCE IN MEDICINE.

To the Editor of the Medical Record:

Sir:—To my mind this must come and very soon for imperative reason, *i.e.* because the common sense of the community demands it. More and more the public is led astray. In excessive specialism, in ultrascientific endeavor, in exaggerated efforts of preventive medicine, sight is lost to curative measures most valuable to ill people, and broadest humanity surely disappears. The teaching, not infrequently, of distinguished leaders, is not always preservative of what is best. Take our Association of American Physicians, and what do we find? Papers read, usually, which could be discussed with profit only by physicians fresh from laboratory research, and to whom care of the sick outside hospitals has relatively minor interest and importance.

Go into advanced city hospitals and what do we find? A corps of ambitious young men who have

captured them and carry the responsibilities of hospital wards, filled with patients of divers sorts and origin, and, therefore, in need of all available knowledge. And yet the consultant physicians and surgeons, in general medicine or surgery, are, as a rule, figure heads, which serve slightly useful purpose. Why? Simply because what they could give is no longer properly valued, *i.e.* wise counsel and guidance. Preventive medicine, rightly estimated, is of primary importance and not medicine, or surgery, which alleviates misery and disease when they occur. And yet to prevent acute or chronic disease, except in limited degree, means complete change of previous modes of life, often practically impossible, or neutralization of seasonable influences. Over the latter we have no control, although they bring now, as always, epidemic diseases, variable as to spread and intensity. At present we require more rational philanthropy and less scientific research in the care and treatment of ill people.

The human machine should be wisely guided and restrained to secure and preserve health. When, from one cause or another, it is not attained or kept, it may be ameliorated, not by subversive and novel methods, but by simple means and judicious control. Wisdom of ages counts, so does experience from wise empiricism. Both have shown indubitable facts, clinically, and carry with them mental and bodily welfare. Every fresh influx of aspiring physicians and surgeons should not attempt to change them. Our noble art must not be a victim of over-weening ambition or of thirst for gold. It must remain true to antecedents and idealism of the best kind.

Beverley Robinson, M.D.

New York.

A CORRECTION.

To the Editor of the Medical Record:

Sir:—In the valuable article in the Medical Record of July 20, 1912, on "Local Anesthesia in the Upper Respiratory Tract," the author credits me with three deaths due to the combined use of cocaine and adrenalin. The three deaths referred to were first reported by me to the Rhinological Section of the American Medical Association in St. Louis in 1910 but were not reported as personal experiences. The error probably occurred through ambiguity in my quoting the cases in my article in the Medical Record of October 31, 1911, on "Tonsil Removal with Reference to Quinine Anesthesia," etc.

I hope Dr. Freudenthal's article will be read by every man using cocaine and epinephrin solutions, as I am sure that most of the members of the profession are not wholly alive to the dangers associated with the injection of these drugs.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCHOOL OF TROPICAL MEDICINE—INGLEBY LECTURE ON PUERPERAL FEVER—STREPTOCOCCUS PUERPERALIS—INSURANCE ACT, CONTROVERSY UNSETTLED—SANATORIA UNREADY—OBITUARY.

London, July 12, 1912.

The Chairman of Committee of the London School of Tropical Medicine, Mr. Austin Chamberlain, issued yesterday an appeal for £100,000 to provide for the extension and efficient carrying on of the work. This school, founded in 1899 by the Seamen's Hospital Society under the auspices of Mr. J. Chamberlain, then Colonial Secretary, has accomplished so much that we may confidently count on more. In no branch of medicine has progress been as rapid in recent years. Expeditions have been sent to study tropical diseases on the spot, and I have informed you from time to time of the important results of their investigations. But additional laboratories are needed, accommodation for the growing number of students, a nursing home for civilians invalided from the tropics, but unable to procure the special attention they require, and it would be well if some small endowment could be established. The chairman's appeal is to the public, and he naturally refers to some of the results of the measures taken and discoveries made. Of his examples cited with a view of enlisting liberal assistance I may quote one—the steps taken in the last three years to stamp out sleeping sickness in Uganda. In one district alone this scourge destroyed 200,000 people out of the population of 300,000. In 1907 the fatal cases in Uganda numbered nearly 4,000, in 1908 they fell to 1,700, and in 1910 to 1,475. A committee formed for this appeal is to meet next Wednesday at the Foreign Office with Mr. A. Chamberlain in the chair.

The Ingleby lecture this year was delivered by Mr. J. Furneaux Jordan, surgeon to the Birmingham Hospital for Women and to the Maternity Hospital. He took for a subject puerperal infection, and discussed its types, incidence, causes, and treatment, preventive and curative. It was a clinical review to some extent which could not fail to interest in every aspect, but I must confine my notice to two. First as to causation. He said the matter for surprise was not that there was so much puerperal fever, but rather that there was not more. We take infinite pains to keep microorganisms from the operation field, but can it be said we do as much to keep them from a cervical or perineal tear? He thought not, and that was the danger. Before a difficult forceps case was over the attendants' hands would often be in contact with the patient's thighs and other parts, and, however sterilized at first, could not continue so to the end. Here the lecturer gave the results of the bacteriological investigation of the uterine discharge as shown in cultures or cultures and films in 21 cases of puerperal fever, nearly all under his own care. All the bacteriological investigations were done by Dr. Mackey, who reported that a streptococcus was present in 17 out of the 21, and was identically the same in all, and quite distinct from other streptococci. Moreover, in any secondary pus, pleuritic fluid, or sputum present, it was found identical with that in the uterine discharge. Furthermore, Dr. Mackey never found this special streptococcus in any other septic cases and only once had he met with it apart from these puerperal cases, and that was in the cerebrospinal fluid of a case of chorea gravidarum. Jordan and Mackey propose to name it *"Streptococcus puerperalis."* As this was found in 17 out of 21 cases, 20 per cent., Mr. Jordan thought it might be regarded as the most frequent cause. At the same time, other organisms have been shown to be causes sometimes. In isolated cases whence comes the infection? This and some other difficulties must be considered. Mr. Jordan suggested that this streptococcus is present in the bowel like the *Streptococcus fæcalis,* and that the puerperal woman is very susceptible to its action. He added that efforts will be made to isolate it from the feces.

The second point I propose to report on is treatment, but this naturally follows, resolving itself into the strictest surgical cleanliness of hands, instruments, and patient's skin over the whole area of the region endangered. The rectum is usually emptied by enema at the beginning of labor, and often enough the bowel contents are again expelled at a later stage. The region of the anus therefore demanded greater attention than had been customary to give it, a bowl of biniodide, 1 in 1,000, should be at hand with big bits of absorbent wool, care of fingers in using; in short, absolute surgical cleanliness in every conceivable way was insisted on. These measures may be called preventive, but the lecturer also spoke of curative ones. I pass over the usual remedies that he mentioned to the consideration of the vaccine method, which seems a corollary of the discovery of the *Streptococcus puerperalis*. The lecturer would employ a vaccine in addition to other treatment. He was so satisfied of its value that he expected stock vaccines would soon be on the market, but he believed more in autovaccines and would recommend an injection of it whenever possible. He quoted three cases where, given early, success was complete, and one to show the advantage of the patient's own vaccine over the stock article. He did not think it an impossible dream of the future that every woman should have at the commencement of labor an injection of the vaccine of the *Streptococcus puerperalis,* which would render her immune to the action of this germ; at any rate, it would do so in 70 or 80 per cent. of the cases.

Insurance problems continue to vex the public, and new protests against the act are constantly put forth. To the domestic servants' opposition is now to be added, among several others, that of the agricultural laborer and the farmer. These loudly protest they want no help, and they are known to be "good lives" from an insurance point of view; at any rate, as far as mortality insurance. But in regard to sickness in later life the question seems doubtful. Clerks in various commercial undertakings are also dissatisfied, and as the act comes nominally into force on Monday next, these and many other wage earners are dolefully contemplating the risk of unemployment. It has been calculated that the scheme will at first most surely increase unemployment and that the promises of sick benefit will be more than neutralized because employers compelled to pay insurance premiums on their servants will no longer feel inclined to extend the assistance they have heretofore so liberally given in such eventualities.

Sanatorium benefit bristles with so many difficulties that an official memorandum has been issued to assist the local committees in "beginning the administration." They are told to arrange for the medical examinations as to the existence of tuberculosis and the appropriate treatment of each patient at home, or in any and what institutions, reporting on the proposed arrangements for the Commissioner's approval. They are to consider provisional arrangements to be employed until a permanent scheme can be brought into operation. This last is to regard a "dispensary unit" and a "sanatorium unit." The former will be for expert diagnosis and treatment; the latter a period of residential oversight in farm colonies, open air schools, hospitals, and other institutions, as guided by the medical officer. Any institution must have been approved by the Local Government Board, and "as regards noninstitutional treatment, the manner of treatment also requires the approval of that department." That board has concurrently issued a memorandum of directions to County and Borough Councils as to their arrangements for the treatment, asking them to prepare schemes for the whole population, not merely for insured persons, in their areas. The most sensible of the various suggestions in this document is that "each County Council should confer at an early date with the sanitary authorities throughout the county in order to obtain full cooperation."

In the House of Commons yesterday there was what is described as "a scene" when Mr. Lloyd George was asked to consent to postpone the act for a few months, as his promised sanatoria are not in existence, and it was held to be wrong to exact the insurance money until they were. He refused any concession and attributed to his questioner a wish which was repudiated and drew upon him the remark he had no right to say so. He declared he had every right, and was charged with falsehood, a word withdrawn at the wish of the Speaker. He was taunted by another member as being "in a temper." A letter of Mr. George to a medical correspondent has been circulated by the newspapers. In this he repeats his declaration that he wishes to do all in his power to secure the cooperation of the profession, but the sting is at the close, where he hints that their refusal may necessitate other measures. The net result of all the controversy for so many weeks is that, with the act coming into force on Monday, the profession is firm and united and the Chancellor as obstinate as ever. There are not wanting certain indications that he is preparing to try some other compromise, but it is now too late to do anything more than wait and see whether he will obstinately persist to the extreme.

It is believed by many that Monday will indicate that the act cannot be enforced at all and that the week will show hundreds of thousands refusing to insure. If so, you will learn by telegraph. Amidst all the confusion and doubt a body calling itself "the Liberal Insurance Committee" has called for a "day of thanksgiving" for the act. Not only so, but has coolly proceeded to appoint to-morrow as the day. Nothing more has been published about this curious proposal, and people asked about it usually treat it as ridiculous or contemptible. Well, there is only a day to wait to "see what we shall see."

The Hon. C. B. Mosse, late deputy surgeon-general in the army, afterward for about 25 years superintending medical officer of the Colonial Medical Department, Jamaica, has died at the age of 82. He was a graduate of Dublin, T.C.D. and member College of Surgeons, 1852. He was in medical charge of the expedition up the Gambia in 1866, and present at the capture of a stockaded town. Next year he was promoted staff surgeon for valuable services during yellow fever epidemic at Bathhurst. He served through the Ashanti War (1873-4) and was at the actions of Essaman, Amoaful, and Ordahon, as well as at the capture of Coomassie. For his bravery in these engagements he was awarded the medal and clasp and C.B. Retiring in 1876 as deputy surgeon-general, he took office as above in Jamaica, where he became member of the Legislative Council. In 1897 he was made a C.M.G. and in 1904 he retired from the colonial service.

6. Actinomycosis Treated with Vaccines. R. Kinnicutt and W. J. Mixter.
7. Three Cases of Pellagra. C. H. Dean.

1. An Idealization of the General Practitioner.—F. S. Meara believes that ethics should enter into the preliminary education of the general practitioner and should be given prominence in proportion to its practical value and not left to the hazard of environment or fortuitous example. The ideal practitioner is he who, about to deal with man, has appreciated the meaning of man and has fitted himself to meet the varied problems man presents; who sees in his capacity for knowing, feeling, acting, and worshipping, the parts in himself, which, developed, make the symmetrical whole and give him contact with all men; who seeking to acquire the facts that constitute the science of his profession studies in their application the object of their application, thus perfecting the art of his profession; who lives clean and acts the golden rule, and who leaves in a grateful memory and an untarnished name his *monumentum aere perennius.*

2. Recent Studies in the Pathogenesis of Epilepsy.—L. Pierce Clark concludes that genuine epilepsy would seem to be dependent upon certain unknown complex heredity factors producing a form of cortical and subcortical instability upon which a variety of endogenous toxins may act, causing the disease. The fit is an exhibition of a reflex action of the disease, and as such should not be seriously interfered with by sedatives *per se.* The sedative treatment of epilepsy is, therefore, to be thoroughly discouraged as long as there is hope of bringing the real clinical pathogenesis of the disease under control.

4. The Regulation of Midwifery.—J. L. Huntington points out that the medical schools are not giving the proper training in obstetrics. The man or the woman who is to take the responsibility of obstetrical cases must be prepared to cope with every emergency which may occur during labor or the puerperium. Anything less than this, according to the author, is a makeshift and must be so regarded in the clear light of modern science. To train women to take care of normal cases only must be fallacious, for who is to make the diagnosis and be sure that the case is normal. It seems hardly right to maintain two standards of obstetrics, one for the poor and ignorant, and another for the intelligent and well-to-do.

5. Hyperemic Treatment of Poliomyelitis.—P. McIlhenny carries out the method of treatment in the following manner: The alimentary canal is thoroughly cleansed; the paralyzed limbs are lightly bandaged with cotton to keep them warm; the patient is given a stimulating liquid diet and strychnine in small doses: cups are applied intermittently to both sides of the spine from the sacrum to the cervical region for one hour daily, and this is continued regularly until muscular soreness has disappeared and voluntary motion in the affected muscles begins to return; the bandages are then removed and massage is begun, a general diet gradually being allowed, and the cupping being continued. The author bases his treatment upon the results he has obtained in five cases.

6. Actinomycosis Treated with Vaccines.—R. Kinnicutt and W. J. Mixter obtain pure cultures of the actinomyces by thoroughly washing separate granules gotten from the pus in five or six changes of sterile, normal salt solution. They have found that a stock vaccine is apparently as effective as an autogenous one, for when the organism has once been obtained in pure culture, it can be left growing in the laboratory to be used when needed. It is impossible to standardize such a vaccine except in a very rough way, because the filaments composing the colonies are not evenly broken up. The routine method of treatment is to give 0.1 c.cm. of the vaccine subcutaneously for the first dose. This is repeated every three or four days, increasing the amount given 0.05 to 0.1 c.cm. each time until a dosage of 0.75 c.cm. has been reached. The authors have treated with vaccine eight cases of actinomycosis: two with abdominal, two with pulmonary, and four with cervicofacial actinomycosis. They find it impossible to draw any general conclusion from these few cases, but it seems that the use of vaccines in superficial actinomycosis does do good. In lung actinomycosis with the severe secondary infection which invariably accompanies it, vaccines are apparently useless.

7. Garbage Disposal. T. M. Koon.
8. Syphilitic Facial Paralysis. C. O. Files.

1. Tincture of Iodine as a Surgical Disinfectant.—F. T. Woodbury has used the U. S. P. tincture on the tonsils for acute and chronic tonsillitis; in the parturient uterus and on extensive lacerations of the perineum; in the cavity following the evacuation of an amebic liver abscess; in the intestine, on the ovary, in the bladder, stomach, gall-bladder, and knee-joint; in fistula in ano and tuberculous osteitis; on compound comminuted fractures from crushing and gunshot wounds, on dressed compound fractures of the skull and spine; on amputations, on corneal ulcers, and in various ophthalmic operations; and on his own hands as a disinfectant before operating. A solution of one teaspoonful of the tincture to a quart of normal salt solution made with pure sodium chloride has been used as a wet dressing in suppurating wounds, burns, and gangrene from frost bite; as a bladder irrigation in acute cystitis; as a vaginal douche, a gastric lavage, a urethral injection, an injection into the spinal canal in a case of epidemic cerebrospinal meningitis; as a nasal spray, a gargle, a collyrium; and as a cleansing solution for flushing out the abdominal cavity after suppuration, and for washing out tuberculous bone sinuses. It makes a good rinsing solution for the surgeon's hands during operations.

3. The Anemic Habit.—H. Brooks believes that long standing anemia leads to a condition of the blood-forming centers characterized by an indisposition to the restitution of the blood to the normal level, even when the primary etiological factors of the anemia are eradicated. This constitutes an anemic habit. Treatment of these cases is difficult because of this tendency, which must be wholly eliminated or lessened before success can follow. Successful treatment in most cases demands closely detailed study, the direct application of the hygienic requirements in each individual case, and the direct attempt must be made to stimulate the blood-forming centers by the development of a tissue demand. Drug treatment or nature alone in these cases of anemic habit is insufficient, but they must be combined for the successful management of the condition. Treatment must in most instances be prolonged and persistent. Relapses are frequent.

4. The Pneumococcus in the Feces.—A. A. Rutz con-

cludes on the basis of clinical observations and bacteriological examinations that there are living and active pneumococci in the feces in acute lobar pneumonia; that tympanites is a constant and important symptom in the disease; that the intestine is the special organ of excretion of the toxins; and that routine rectal injections from the onset of the disease, together with other accessory measures intended to reduce the toxemia and tympanites, materially influence the course and lower the mortality of the disease.

5. Autotherapy in Neurosyphilis.—W. Browning and W. Lintz present a second communication on this subject. Their method consists in utilizing as a therapeutic agent administered hypodermically the spinal fluid removed by lumbar puncture from cases of syphilis of the nervous system. The principles upon which this method of treatment is based were discussed in the former article (see MEDICAL RECORD, May 4, 1912, page 861.) The authors do not claim that this method is suitable for all cases of neurosyphilis, but claim that it gives invaluable results in selected cases. There are three very material limitations to its use: (1) The stock of antibodies in any given case is soon reduced or temporarily exhausted, and furthermore is not very rapidly renewed. (2) Some apparently suitable cases fail to show any, or any important content of antibodies in the spinal fluid. In such cases no improvement of the main trouble is obtained. (3) The antibodies of the administered material disappear rapidly from the system. In general, and if a full amount (say 25 to 50 c.c.) of spinal fluid fairly rich in antibodies is injected, signs of improvement become evident toward the end of the first week following the injection, often in four to six days; and in some cases the main benefit appears to be completed in about a week after it begins. This may be called the primary gain, but a gradual secondary improvement may go on for some weeks at least. An important side effect of these injections appears in the improvement of the bowel movements. This has been observed in all classes of cases, whether of specific character or not, though the degree of intestinal stimulation may vary considerably.

13. A Useful Procedure in Submucous Resection of the Nasal Septum. F. C. Smith.
14. Thymol for Tænia Saginata. W. Allan.

1. Puerperal Septic Thrombophlebitis.—C. J. Miller discusses the treatment of puerperal septic thrombophlebitis by means of ligation or excision of the pelvic veins. The success of a similar method of treatment in pyemia of otitic origin has naturally suggested the use of the method in puerperal cases not pathologically different except in location and extent. As to the indications for and technique of the operation, practically all agree that intervention is advisable as soon after diagnosis as possible. Inflammatory exudates contraindicate operation and ligation is of little value except in the pure forms of thrombosis. If lung abscess or pneumonia has occurred the case is then hopeless. The practical deduction from the study of the literature is to operate in the acute stage if the general septic features do not predominate and to watch constantly for signs of localization. Whether ligation or excision be done depends on circumstances; the latter procedure is reserved for cases presenting periphlebitic processes, cicatrices, abscesses, etc. While the available figures of operations are not specially encouraging, a detailed analysis of the cases throws a different light on the subject. It is necessary to exclude the hopeless cases, for many of them are practically autopsies. Deducting cases of cava thrombosis, acute pyemia, and faulty ligation there was a general mortality in the author's collected cases of 21 per cent., dropping to 8.5 per cent. when only one or both ovarian veins were ligated, but reaching 31 per cent. when both hypogastric veins required ligation.

3. Tuberculous Meningitis.—J. H. W. Rhein comments upon the results of the histological examinations of nine cases of tuberculous meningitis, one of which was diagnosed as pneumococcus meningitis. He believes that it is possible, if not probable, that the meningitis in these cases is due to a mixed infection and does not originate solely from the tubercle bacillus or its toxins. The rapidity of the course of the disease in adult cases is very unlike the slow chronic process characteristic of tuberculosis of other organs. The cellular changes of the exudate are not absolutely characteristic and are not typical of the tuberculous process. Vascular changes were observed in seven of the nine cases. These consisted of thickening of the walls of the arterioles and of some veins. Perivascular round-cell infiltration was quite commonly observed. In one case the lumen of the small vessels was obliterated. In another there was hyaline degeneration. Distention of perivascular spaces was noted in seven cases and in several there were other evidences of encephalitis. Plasma cells were more or less present in six cases.

5. Adipositas Cerebralis.—A. Gordon reports a case of tumor of the hypophysis presenting the clinical symptoms of Fröhlich's syndrome, otherwise called dystrophia adiposogenitalis, which belongs to the group of adipositas cerebralis or all cases in which the deposit of fat is due to a cerebral cause. Cases of adiposity and genital hypoplasia have been observed more frequently in connection with hypophysis disease than in that of other ductless glands. When one of these is affected the others are likely to be affected as well. The symptoms in the author's case developed very irregularly, suggesting different diagnoses: paresis, multiple sclerosis, and brain syphilis. The correct condition was realized when the patient's adiposity appeared and this with the bitemporal hemianopsia and the sexual infantilism included the case among one of the forms of Fröhlich's syndrome. Other interesting phenomena were the glycosuria which, though slight, was evident throughout the five years of observation and the profuse perspiration from which the patient suffered intensely, regardless of exertion or temperature. At the autopsy, besides the large angiosarcoma of the hypophysis of which no healthy tissue could be found, there was enlargement of the thyroid and of the adrenals.

8. Primary Carcinoma of the Lung.—B. M. Edlavitch reaches the following conclusions: 1. There is abundant evidence of the occurrence of primary carcinoma of the lung as a definite pathological entity. 2. This type of tumor originates mostly in the epithelium of the bronchi, not infrequently in the alveolar epithelium, and sometimes in the epithelium of the bronchial mucous glands. 3. It is about three time more common in men than in women. 4. The right side is affected about twice as often as the left side. 5. It may involve part or all of a lobe or an entire lung; it is usually unilateral and often fairly well circumscribed. 6. The bronchial lymph-nodes are practically always involved, but other parts, principally the brain, which seems to be especially susceptible, may become in-

volved by secondary metastases. 7. Pleural effusion, mostly hemorrhagic in character, occurs quite constantly in association with this condition. 8. In suspected cases the presence in this pleuritic fluid of large epithelial cells may be regarded as of diagnostic importance.

9. **Aseptic Intestinal Anastomosis.**—W. D. Gatch has found that aseptic intestinal anastomosis by any method of suture is theoretically impossible, but the amount of contamination can be so reduced that cultures taken at the line of suture are sterile. Descending invagination, if a proper technique be employed, may be used to remove pieces of bowel several inches in length with excellent immediate and late results. It is possible to perform lateral and end-to-end anastomoses of the intestine aseptically and without the use of special instruments so as to secure practically the same operative results as are obtained by standard non-aseptic methods for these operations, and with no increase in the difficulty of the technique.

10. **Operative Treatment of Joint Fractures.**—By F. J. Cotton. (See MEDICAL RECORD, June 29, 1912, page 1249.)

11. **Surgery of Bones and Joints.**—By L. W. Ely. (See MEDICAL RECORD, June 29, 1912, page 1249.)

12. **Intestinal Complications in Gynecological Operations.**—L. S. McMurtry states that these complications may be strictures, obstructions, fistulas, or anastomoses. They cause sometimes serious difficulty in removing tumors, especially of the ovaries, and are constantly found matting the bowels together in advanced ovarian cancer and peritoneal tuberculosis. The frequency of appendicitis as a gynecological complication of tuboovarian disease is generally recognized as a forceful indication for the suprapubic rather than the vaginal route of operation. The omentum and sigmoid flexure are the parts most frequently involved in adhesion, the omentum being the most efficient means of warding off infection of the other viscera, and adhesion of the sigmoid and rectum is so common with tuboovarian disease as to be distinctly a gynecological condition. Extensive gluing together of the intestines after general peritonitis is a result sometimes of Nature's failure to absorb, and forms a distinct type embarrassing operative procedures, which may also be caused by ovarian and uterine neoplasms. The author advises as prophylactic measures against the formation of adhesions in gynecological work the following: As far as compatible with safety, operations should be avoided in the acute stages of inflammatory diseases and deferred to a period when Nature has removed gross exudates. Unnecessary handling, wiping, and packing off of peritoneal surfaces should be avoided in operations. The violence of retractors and unnecessary exposure should be avoided. Blood clots beget granulation tissue and adhesions and should be gently and carefully removed. Drainage, especially with gauze, produces adhesions and should be applied only when definitely and positively indicated. In dealing with adhesions in the course of operation, the greatest care should be taken to limit traumatism, using sight when possible and working deliberately. The greatest source of adhesions is unrecognized injury to the intestinal coats. A thorough knowledge of the best modern technique is essential. To avoid agglutination of separated surfaces is not always possible, but perhaps the most efficient procedure is applying a layer of sterilized petrolatum over denuded surfaces.

7. Observations on the Neuron. H. Campbell.

1. **Duodenal Perforation.**—D'Arcy Power reports the histories of five cases of this condition operated upon by him during a short period of time. Each case occurred in a man in the prime of life, emphasizing the fact that acute perforation of a duodenal ulcer is much commoner in men than in women. Each patient had been in good health up to the time of the disaster. Previous indigestion is unusual in duodenal ulceration. This symptom never has the same prominence as in cases of perforated gastric ulcer. The onset of pain is sudden and entirely without any exciting cause. It is severe and is associated with considerable shock. Gentle palpation of the abdomen reveals that the upper part of the right rectus is a little more tense than the corresponding part on the left side, while there is a definitely tender spot above the umbilicus and to the right of the middle line. The abdominal muscles become more tense as the shock passes off, and a new and very misleading symptom appears, for the patient now begins to complain of pain which he localizes in the right iliac fossa. On this account many cases of acute duodenal perforation are diagnosed as cases of acute appendicitis. This mistake may be avoided if one remembers that in acute appendicitis the pain, tenderness, and rigidity are limited to the lower part of the abdomen, though all the symptoms may extend across to the left side, while in acute duodenal perforation, although pain and tenderness may be felt in each iliac region, there is a point of maximum pain in the right hypochondrium, and there is at least increased resistance over this area. The next misleading point in a case of acute duodenal perforation is the manner in which the abdominal symptoms subside as the initial shock passes off.

2. **High Blood Pressure and the Commoner Affections of the Arteries.**—H. French is certain that high arterial pressure can be reduced safely only when the muscle of the arterial coats is still muscle, though it may be out of training and stiff. As long as it is muscle it may be rendered supple again by arterial gymnastics, and so brought back under the control of the vasomotor system, to the great relief of the heart. When, however, the tunica media of most of the arteries, particularly those of the splanchnic area, is fibrous and no longer muscle, a high blood pressure becomes a necessity if the patient is not to be permanently invalided. If one relies solely upon the "toxic" and the "increased peripheral resistance" theories of arteriosclerosis and high blood pressure, one may often treat the patient on the wrong lines. The correct lines of treatment are as follows: (1) Prevention by moderation in eating and drinking, a due alternation of brain work with physical exertion daily. (2) Relief in the earlier stages by carefully considered steps that may be classed together under the heading of "arterial gymnastics." (3) Recognition of the fact that when the stiffening stage has passed and fibrosis is already established a high blood pressure is to a greater or less extent a necessity; that it has to be maintained by the heart; that it could be lessened by lessening the work of the heart, as by invaliding the patient or putting him to bed; but that if the patient is to continue life in anything like its full activity the heart must be enabled to maintain a high blood pressure, for which purpose iodides, nitrites, and so forth are relatively useless; cardiac "training" by regulated massage, exercises, being far more important, and the chief drugs to rely on when the heart symptoms are well developed being those which increase the force of heart beat, especially full doses of tincture of digitalis.

3. **Coincident Tubal and Intrauterine Pregnancy.**—R. L. Knaggs and W. W. Walker report a case one of the most striking features of which was the association of a tubal pregnancy of unusual character with a uterine pregnancy

of a later date. The development of the intrauterine pregnancy followed so closely upon the onset of degenerative changes in the tubal fetus and the nature of the case was made so clear at an early stage in consequence of the enforced abdominal exploration, that even if there were no other points of special importance the case would be a contribution of considerable interest to the subject of tubal pregnancy. Attention in the main, however, cannot fail to be concentrated upon the tubal condition. The tubal pregnancy reached the highest point of its development without rupture of the tube. The last stage of the tubal pregnancy was also unusual. A lithopedion is rarely completely intratubal, but more commonly is contained in a sac which is formed by peritoneal adhesions and false membrane. In this it may lie harmless for years. But where suppuration occurs the pus may open in various directions and the fetal bones be discharged through the skin, the bowel, the bladder, or the vagina. The peritonitis is local and limiting. In this case a small perforation resulted evidently from ulceration of a sharp edge of bone and a general peritonitis of a not very virulent type resulted from the flooding of the general peritoneal cavity with escaping adipocere.

6. **Neosalvarsan.**—J. McIntosh, P. Fildes, and H. B. Parker note that in the evolution of neosalvarsan the chief object in view has been the achievement of increased solubility and a neutral solution. The means by which these improvements have been brought about is that frequently used to convert insoluble benzene derivatives into soluble—namely, the introduction of a sulphoxyl radicle. In this instance this was carried out by means of acid sodium formaldehyde-sulphoxylate, $CH_2(OH)O.SO.Na$. Neosalvarsan contains one such group attached to an amido radicle. The powder is yellow in color and less fine than salvarsan, so that on shaking the capsule a definite rattle is detected. In general the importance of neosalvarsan is the diminished toxicity to man, enabling a further step to be taken toward the more frequent attainment of a more intensive treatment of early syphilis. Generally, in primary syphilis two initial doses may be given, followed by a third at an interval of four weeks. In secondary syphilis three injections are sufficient at first, with a fourth eight weeks later; while in tertiary cases the treatment should be continued every two to three months after the initial course until a negative Wassermann reaction has been obtained.

5. **Parotitis Associated with Glycosuria and Acidosis.**—L. M. Routh reports a case presenting these conditions in a man aged 58 years. At no time in the past had symptoms ever suggested the presence of sugar in the urine, and on several occasions during other ailments the routine examination of the urine had shown it to be healthy. The patient was a stout and rather active man who on April 13th had definite fullness but no tenderness over the site of the right parotid. One week later the swelling gradually increased in size and involved also the submaxillary gland. There were considerable pain and constitutional disturbance, the temperature reaching 103°. On April 28 the patient had considerable thirst and the urine which was passed frequently and in large quantities was found to contain a trace of albumin and a large quantity of sugar. Diacetic acid and acetone were also present. Exploration showed that there was no pus present in the parotid. The patient gradually improved, and on May 13 the parotid swelling had subsided and the urine was free from sugar. The following question suggested itself: Did the parotid inflammation cause some autointoxication with secondary effect on the metabolism of the pancreas as a cause of the glycosuria? There is, of course, some fundamental correlation between the parotid gland and pancreas, in that they both secrete a juice materially aiding in the digestive processes. Another possibility is that the parotid and submaxillary also furnish an internal secretion, the temporary disorganization of which may cause glycosuria. The fact that the left parotid and submaxillary glands were not involved, and that their internal secretions were therefore intact, would perhaps favor the former view. With regard to the origin of the parotitis, the author is uncertain whether to attribute it to the initial draught or to an oral infection through Stenson's duct.

6. **Clinical Importance of Electrocardiography.**—T. Lewis notes that galvanometric examination of the heart is important from many points of view. It may give indications of enlargement of the walls of one or other cardiac chamber. It may accurately locate small lesions in the musculature. It informs one when the heart beat starts at the normal impulse center or away from it: in the latter case it indicates that the rhythm is no longer under the normal nervous control—a fact which is of fundamental importance in the management of a case. It gives a separate record of contraction in auricle and in ventricle, and accurately defines the time relation of contraction in one chamber and the other; thereby it frequently elucidates physical signs which otherwise remain obscure. It provides a perfect means of ascertaining the functional efficiency of the auriculoventricular bundle, the sole conducting tract upon which the ventricle depends for the reception of impulses which start its contractions. It enables one to differentiate between separate forms of slow and rapid heart action, which are of totally different significance. It provides an analysis of every form of cardiac irregularity, an analysis which is unrivaled in its precision by any other method. While the information derived from it relates essentially to the condition of the muscle, the method is often helpful in the diagnosis of lesions of the valves. It brings one into nearer contact with the functions of the heart muscle than does any other clinical method. It is, in short, a precise means of studying the heart as a living and moving organ.

Berliner klinische Wochenschrift.

June 24 *and July* 1, 1912.

Inulin as Diabetic Food.—Strauss reports at length on this subject with especial reference to the prevention of acidosis. Inulin, a polysaccharide of levulose, was recommended in diabetes as far back as 1874, but only quite recently Naunyn and Socin decided after an extensive test that it had little value in nourishing a diabetic. Their criterion, however, was the degree of sugar elimination. The question of the utilization of inulin in the healthy has also been a debatable one, for it has been stated that it resists the action both of saliva and pancreatic juice. The author has studied the subject from every angle. He concludes that in most cases diebetics do remarkably well on inulin, possibly better than on oatmeal or wheat flour porridge. Since his good results must be due to technique, he recommends inulin periods of four to eight days with short intervals of alternation with other foods. Inulin should be given in other dishes, such as eggs cooked in various ways, fruit stews, and vegetables. The protein content of the food should not be excessive. In the intervals he uses the same foods minus the inulin and does not substitute any carbohydrate for the latter. The daily ration of inulin is 50 to 100 gms. The inulin bread which has been

used by others he does not like, as he finds bread bad for tolerance. He would reserve inulin for severe cases, especially with acidosis threatened or actually present. That this condition is benefited is unmistakable.

Gastrospasm in Cholecystitis and Cholelithiasis.—Schlesinger in the course of radiographic studies of gall bladder disease chanced to observe in two patients total spam of the stomach, apparently as a reflex from the painful condition of the other organ. One patient, a woman aged 57, had suffered for thirty years with attacks of gastric cramps unconnected with eating. The attacks in the other patient had only recently appeared and the spasmodic state was recognized in the radiograph, having already been noted by palpation. Naturally it became necessary to exclude gastric ulcer and perigastric adhesions. These spasms are not necessarily painful, for gastrospasm has been recognized in radiographs of hour glass stomach, etc., and it is possible that isolated gastrospasm is not painful. On the other hand it no doubt adds at times to the pains of acute cholecystitis and hepatic colic, and the author has reason to believe that this is true also of renal colic, appendicitis, and pancreatitis, all of which conditions are accompanied by vomiting. Hence gastrospasm should be of diagnostic value in calling attention to the likelihood of some acute abdominal affection.

Trephining for Simple Punctured Wound of the Brain.—Mühsam reports a case of this sequence along with others in which the presence of complications furnished the indication. It is of course exceptional for a stab wound to traverse the cranial bones and enter the brain substance. The knife in this case passed through the temporal bone and paralyses of the left facial nerve area and left arm and leg soon supervened. Several days later convulsions developed in the paralyzed area, then becoming general. The *x*-ray showed the presence of a hematoma in the temporal region. As the convulsions continued to recur serially the patient was trephined and made a prompt recovery.

Absence of Urinary Pepsin in Diabetes Insipidus.—Rosenthal refers to the most recent view that diabetes insipidus is due to a peculiar form of renal insufficiency which stands in the way of excretion of typical concentrated urine; also that this peculiarity may depend in some way upon some internal secretion, since diabetes insipidus has been seen in lesions of the hypophysis. It has also been noted that pepsin and amylase may be absent in this kind of urine, and this point the author has chosen for a special study. The first patient to appear with diabetes insipidus was a man aged 27, healthy and of sound stock. His only disorder was polyuria and thirst. Repeated analyses showed complete absence of urinary pepsin and only an occasional trace of amylase. It is not yet certain that this absence of ferments can be given pathognomonic significance as the material thus far analyzed by the author and his predecessors is much too scanty. If further research is corroborative we shall, perhaps, have a resource for distinguishing between diabetes insipidus and other forms of simple polyuria. The author does not pretend to give a rationale for this absence of urinary enzymes.

Spasmophilia.—Meyer of the Berlin Orphan Asylum has studied this subject from recent literature in respect to its bearings on the tetany of nurslings. He first reviews the work done on the parathyroids and thyroids in this connection. It cannot be shown that these bodies show any constant anatomical alterations, but a functional insufficiency is highly probable, dependent on an inborn inferiority. The subject of calcium metabolism is not reviewed. There is a conflict of testimony at present. The weight of evidence still shows that poverty of calcium salts is in some way associated with spasmophilia, but other factors must be involved, *i.e.* spasmophilia means more than simple defect of lime salts. A third subject is the association of tetany with other organs and functions. A certain parallel exists between tetany and ergotism, and the former has been brought in relation with the circulation in the blood of a hypothetic vasoconstricting substance —perhaps more than one. Thus some cases of tetany could be explained by exogenous poisons and intestinal autointoxication, while others must depend on strictly endogenous poisons, as in tetany from extirpation of the parathyroids. It is, of course, not impossible that adrenalin behaves as a vasoconstricting agency when present in a certain degree of excess in the blood. Under diagnostic procedures Schlesinger's leg phenomenon is a new criterion. If the extended thigh is bent strongly on the hip there is an extensor spasm at the knee joint. This adds another to the several reflex tests now used in identifying spasmophilia. The part played in tetany by smooth muscle, including the heart, has now become recognized. The sympathetic nervous system and even the vegetative functions are also known to be affected in tetany, so that the latter appears to be almost a universal condition. Under treatment it does not appear that anything important has recently transpired. Calcium bromide has been recommended as combining food and medicament.

Tracheitis Gummosa.—Stumpf relates a case of this somewhat obscure affection. A healthy man not believed to have had syphilis by himself or others, but whose older children had shown a high mortality, had several profuse hemoptyses, the last of which proved fatal. Section showed syphilitic ulceration of the trachea near the bifurcation. The points of note were the blood-tinged sputum which preceded for some days the first hemoptysis and the total absence of pulmonary or laryngeal tuberculosis. A histological study showed that a granulomatous tissue had been deposited in the trachea and had undergone caseation and subsequent ulceration. Tuberculosis and simple granuloma formation could be excluded on histological grounds alone. Aside from syphilitic aortitis the patient was apparently free from other lesions.

Münchener medizinische Wochenschrift.

June 25 and July 9, 1912.

Slow Escape of Pleural Empyemata into the Lungs.—Schmidt after mentioning the brusque escape of empyema pus into the bronchi in which the fluid is sometimes expectorated by mouthfuls, confines his attention to the slow, deliberate type of escape as illustrated by three personal cases. This termination is of course rare—how rare does not seem to be established. One patient with symptoms of pleurisy began to spit pus. Pus was obtained by puncture. The sputum contained no tubercle bacilli or elastic fibers. It was free from odor. Physical diagnosis including *x*-raying showed a clean cut pleural exudate with no complication other than the purulent sputum which must therefore have proceeded from the empyema. The sputum remained purulent for a number of days, slowly disappearing. There is no mention of thoracentesis aside from the diagnostic puncture. In the second case the trial puncture brought away fetid pus. Aspiration was practised with subsequent insufflation of sterile air and iodine fumes. The pus, tested in the incubator for gas forming bacteria was found to be practically sterile in this respect. The patient did not begin to spit pus until after the puncture. This was free from odor, contained no tubercle bacilli or elastic fibers. The *x*-ray in this case showed air in the pleura, a fact which in the absence of gas forming pus would suggest the entrance of air through the ruptured lung parenchyma. Points of special interest comprise further the indifferent character of the pus in the sputum. This contained nothing whatever upon which any sort of microscopic diagnosis could be based. The fact that in one case there was no purulent sputum until after the trial

puncture would cause strong suspicion that the latter had involved the lung. It is further recorded that in the first patient the sputum became tinged with blood after the puncture. There seems indeed no reason why an empyema of the type described should rupture into a sound lung. Associated pneumonia with abscess formation would explain the complication but this possibility seems to have been excluded. With the evidence at hand two of the three cases must have been due to rupture into the air cells of unknown mechanism.

Epilepsy from Electric Currents.—Jolly discusses this subject as a document to the causation of epilepsy from electric traumatism of the cortex in presumably sound subjects. Much care is necessary to exclude traumatic psychoneurosis and hysteria. A young motorman touched a live wire in the electric trolley system. Aside from the usual burns he had severe headache and abdominal pains for a short time, but was soon able to resume his duties. Two weeks after the accident he suddenly became prostrated and lost consciousness. He no doubt had an epileptic attack but there were no witnesses. The post-epileptic state was in evidence and a few days later he was seen to have a convulsive fit. He also began to have nocturnal attacks, and in fact within a very short time became a confirmed epileptic unfitted to earn his living (capacity reduced to one-third). Traumatic psychoneurosis was readily excluded. The patient's mental faculties show some deterioration as a result or concomitant of the frequent seizures. The number of volts he received of the alternating current were from 450 to 500. Much less than this quantity has often caused death. There are a few similar, more or less questionable cases on record. Convulsions at the time of injury are of course a different matter. These have also been seen in lightning stroke. It is of course impossible to prove that the author's patient was not a latent epileptic but all facts point in the opposite direction.

Interesting Case of Tetanus.—German describes a case with this title. The nature was at first obscure and the diagnosis was influenza, made from the association of sore throat and myalgia. The only possible post of entry for tetanus virus was a slight, already healed wound of the little finger. The evidence of tetanus were soon unmistakable. The jaws were not fully locked, and patient took liquid food through a nursing bottle. Although apparently a very sick man, the temperature was not high. There was profuse sweating. The patient had seizures of screaming which he could not suppress. They occurred at regular intervals and were believed to be due to the irritation of some portion of the central nervous system, in connection with the temperature center and perhaps the vasomotor center. The cries were not due to suffering, which had not been marked. The case was of the chronic type and slowly improved, perhaps without reference to the treatment. Serum was given, but did not seem to modify the course of the disease. The atypical character was pronounced. The enormous degree of sweating doubtless kept down the temperature and toxemia. The cries were much like the initial cry of epilepsy and the cry of the katatonic.

Sarcoma of the Humerus Successfully Treated with X-Rays.—Bülow-Hansen reports the case of a man whose life was perhaps saved only to be forfeited soon afterward by an accident. This enabled a confirmation of the diagnosis. Patient was a boy of 10 years who had begun to suffer with pain and impaired function in his right shoulder. The *x*-ray showed the presence of a probable sarcoma of the head of humerus. Operation was refused as the boy's right arm might have been permanently disabled and he was an only child. There was already some atrophy from disease. As a compromise a short period of treatment with the rays was instituted. A steady, uniform improvement began, checked up by frequent radiographs. The area which was rarefied by the tumor began to fill up anew with bone. After the fatal accident, the specimen was obtained, and the diagnosis was confirmed. Osteomyelitis, tuberculosis and syphilis could be excluded. The treatment had caused neither inflammation nor necrosis. Histologically a cure could not be predicted as tumor tissue was still present. The disease, however, had been much more than arrested, for the patient had recovered the use of his arm, and his general health, which had begun to fail, was restored.

Clinical Method for Estimating the Time of the Blood Circulation.—Bornstein has tested a new method for determining in individuals rapidity of circulation. Thus far one can form only an idea of the least time required for the cycle. The principle involved is the inhalation of carbonic acid. As soon as the latter reaches the respiratory center quickened respiration will at once be evident. Attempts to measure the rapidity of the circulation go back for many years, but inhalation of gases as a measure is doubtless new. Naturally but one-half of the circulation is measured by this method. It requires a few tenths of a second for the blood to travel from the lung capillaries to the nerve centers. The author appears to believe that this method is capable of considerable amplification.

Deutsche medizinische Wochenschrift.

June 27, 1912.

Spontaneous Cure of Cancer.—Theilhaber, after calling attention to three cases seen by him in which patients remained permanently cured after hysterectomy for cancer, despite the fact that outlying nodules of disease must have been left behind, goes on to describe an inoperable case of this disease in which he obtained a cure without the knife. The treatment consisted of curetting and thermocauterization, followed with a course of arsenic injections (cacodylate of sodium hypodermically), and the use of the hot-air douche, hot-water injections, and sitz baths. Under this treatment the parametrium, which had been infiltrated with cancer once more became supple and the uterus could be freely moved. The general health improved until it became complete. The author, as the title implies, gives credit to natural forces for the cure, but the treatment was none the less responsible. The efficacy of hot air is apparent in a case of beginning recurrence of cancer of the breast in which complete arrest followed the treatment. Similar cases reported by others lead the author to urge a more energetic after treatment of cancer, especially after incomplete removal. He enumerates many resources. To make the scar supple he uses fibrolysin. The hot-air douche tends by causing active congestion to render the local nutrition normal. He would use oöphorin, arsenic, mountain air, sun baths, and sea baths.

Gout Tophi in the Eyelids.—Ebstein discusses the rarity of this complication or of its recognition, as ophthalmologists and dermatologists give only a perfunctory mention of the subject. There should be no real diagnostic problem, although the condition resembles ordinary milium. English authorities on gout, such as Garrod and Duckworth, appear to be familiar with tophi in the eyelids and mention their close resemblance to milium and small atheromata. In the illustration of the author's case the resemblance to a small sebaceous cyst of the eyelid is marked. Diagnosis was evident from the presence of tophi in the ear, but the deposit was removed and examined. Despite the statement of Hirsch that removal is useless because of certain recurrence this sequel did not develop.

The Collapse Action of Hormonal.—Zuelzer who introduced the peristaltic hormone into medical practice, comes to its defense in connection with the fatality re-

cently reported. Hormonal has now been used by the intravenous method over 4,000 times without any untoward reports. Then, suddenly, cases of collapse begin to appear in literature, including the fatal case. Should these accidents be set down to the pure drug action or to impurities or technical errors due to carelessness? The author has always insisted that hormonal be thrown into the vein drop by drop. But even with all technical precaution he himself had four cases of collapse in quick succession. A laboratory investigation showed the presence of an albumose upon which was placed the responsibility for the untoward phenomena. This appeared to be formed during the process of manufacture. All the preparation on hand was taken off the market, and a new supply thought to be free from impurities and danger when properly used, will be substituted.

Fulminating Psychosis with Pemphigus Acutus.—Landsbergen relates a case of psychosis developing in a subject of possibly tainted stock—although there was no absolute evidence to this effect—upon a somatic basis, also expressed by an outbreak of pemphigus. The psychosis was in evidence first, although a marked failure in general health accompanied it. There was an acute phase of excitement, which began to yield and bade fair to end in recovery. At this juncture the eruption first appeared, accompanied by evidences of severe infection. Strange to relate, despite high temperature and the recent acute psychosis there was none of the delirium which was confidently expected. This was the more surprising because the patient's mind had not been fully restored. The pemphigus ended fatally, a termination which had been anticipated from the association of this eruption with high temperatures, arguing the existence of a septic process. The blood contained hosts of staphylococci. Patient probably had a special disposition toward the formation of blebs. The rationale of the development of the psychosis is obscure. That it was connected with the sudden failure of nutrition seems obvious. The way was also paved for a blood infection (from an unknown focus) which manifested itself chiefly by acute septic pemphigus.

The "Signe du Sou" in Pleuritis Exudates.—Slatowerchownikow refers to Pitres's sign first described in 1898 and obtained as follows: An assistant holds firmly against the thorax of the pleuritic subject about to be examined a small copper coin. He strikes this with a second coin, while the examiner applies his ear to the opposite side of the chest at the same level. Certain acoustic phenomena become noticeable. If the sound has to pass through spongy or alveolar tissue it becomes muffled, but if a collection of gas interposes it becomes intensified. If a solid mass or liquid effusion interposes a distinct metallic clink is heard. The sign has been used chiefly in pediatric practice, where it is of value in that it makes up in part for inability to get the pectoral fremitus. The author who has tested the resource in the medical clinic at Kiew gives his conclusions as follows: The "signe du sou" is a very valuable test for exudate in the pleural cavity, including the determination of its boundaries, and is superior in this respect to percussion and the vocal fremitus. It will enable us to do away with trial puncture.

Diagnosis of Malignant Pleural Tumors.—Huismans sums up a clinical and pathological study of this subject as follows: Of two cases investigated, both were pronounced clinically to be primary endothelioma of the pleura. Autopsy, however, showed that in case I the tumor was a carcinoma, secondary to a latent cancer of the stomach. Case II proved to be a primary cancer. In the clinical presence of these cases the questions arise: "is the growth primary or secondary?" and "is it epithelioma or endothelioma?" The error in the first case was unavoidable before death. The distinction between cancer and endothelioma may be futile, for very recent studies appear to show that at least the endothelioma so-called grows from the epithelium of the pleura.

Successful Sterilization of Diphtheria Carriers.—Petruschky of Danzig states that after long efforts he has succeeded in getting authority to hold diphtheria patients in the city hospital until they should be completely freed from bacilli. A young woman with tonsillar patches who presented bacilli in the throat was found to be a potentially dangerous carrier long after her recovery. A culture of her own bacilli was made, killed, and sterilized, found to be harmless to guinea pigs, and injected subcutaneously without reaction of any sort. A second was given four days later. Six days after the first injection the patient's throat and nose were free from bacilli and she was discharged. In a number of other cases of acute carriers so-called the same results were obtained. To sterilize a chronic carrier might prove to be a different proposition and such cases can only be located by accident or by testing a large number of people. One was finally encountered, a tuberculous suspect with diphtheria bacilli in her sputum. She was free from tuberculosis by all the usual tests. Attempts were first made to improve her nutrition, but these failed. Injections were not ventured, but dead cultures of bacilli were rubbed into the skin and within a few weeks the sputum became sterile in respect to diphtheria. Her nutrition improved notably.

Kocher's Present Work in Strumectomy.—At the close of an article on goiter and its treatment Kocher states that he completed his fifth thousand last March. In one series of 603 uncomplicated cases, many of whom were, however, severe, he did not lose a patient. There were 26 cases of malignant struma in the series and 19 second operations. In a series of 91 cases of intrathoracic struma he lost three patients, but in none of the cases was the operation itself the cause. Thus in all cases usually termed plain goiter there was practically no mortality from the operation in 736 interventions. The goiter heart of ordinary goiter is no longer a contraindication if the operation can be done seasonably. There is no summary of his complicated cases in which there was doubtless more or less operative mortality. The author closes with the statement that medical treatment is sufficient for slowly progressive goiters which do not cause stenosis, and often yields brilliant results.

Röntgen Studies of Ingesta and Excreta.—Schwarz gives a subject a certain ration of food and traces its progress through the alimentary canal. In a young, healthy subject, who has regularly each forenoon a formed stool, most of the food taken on the previous day up to the time of the stool lies in the rectum and lower sigmoid. But the balance may be seen scattered through the entire colon. The morning stool does not empty the bowels, for only the accumulation at its lower end is evacuated. Above this mass the small scattered lumps of fecal matter linger, to be incorporated in time with the bulk of another day's ingesta as it passes downwards. Not until the third day do the entire ingesta of a given day leave the body. Hence each morning stool is made up in part of food eaten two days earlier. In order to demonstrate these results, the author says, bismuth has of course to be mixed with all the food ingested, and the amount and kinds of food are standardized.

Bactericidal Action of Radium.—H. Chambers and S. Russ conclude from their experiments that the emanation in concentrations of less than a milli-curie per cubic centimeter has a marked bactericidal action. Agglutination of bacteria in distilled water is an early sequel to the irradiation. Bacteria are more quickly destroyed by the emanation than are opsonin and leucocytes.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

The Effect of Trauma on Sugar Excretion.—Ebstein tells of a diabetic in whom trauma was followed by a neurosis, and as a consequence, the excretion of sugar was markedly increased. He thinks that any injury to a diabetic *may be* followed by rapid exacerbation of symptoms, but such result need not always take place. Ebstein warns against acceptance of a single examination as proof of increase in elimination of sugar, for changes in the amount of sugar excreted are frequent in the usual course of a diabetes. Moreover, mere increase in excretion of sugar need not change the prognosis in any individual case; such other data as the excretion of acids, albuminuria, loss of weight, etc., should be likewise ascertained.—*Zeitschrift für Versicherungsmedizin,* April, 1912.

Life Insurance and Carious Teeth.—A. M. Nodine, D. D. S., says that life insurance medical examinations have one very weak link, namely the failure to appreciate the fact that diseased teeth and gums are constant and insistent menace to the health of an individual, as well as to his neighbors. Nodine says that the present great function of a medical examination for life insurance is to guard the company against insuring any applicant with any illness, disease, disorder or condition that their mortality tables show and increased medical observation shows, tends to shorten life. To limit such examinations to such negative function alone is a very short-sighted policy. The medical organization should be used for other purposes, namely: to suggest to the applicants that if certain conditions are corrected, they will be accepted by the company. Secondly, after the applicants are accepted, they should be examined at certain regular intervals so that any condition or disease that may shorten life may be anticipated. Thirdly, policy holders should be provided proper medical treatment if they have fallen sick. Fourthly, a general educational campaign should be instituted acquainting the public with the proper mode of living, proper personal hygiene, etc.

The establishment of sanatoria for tuberculous policy holders, and the establishment of a "conservation department" show that the insurance companies are beginning to see the possibilities of their medical departments. Nodine thinks that in many conditions, which exclude an applicant from insurance, septic mouths and carious teeth play a very important rôle. In tuberculosis, the accumulation of calculus and food and the presence of carious teeth and necrotic roots supply a very efficient reservoir of infection for either the structures of the mouth or other parts of the body. The stomach, the tonsils, the bronchi may be all secondarily infected from such pockets of disease.

Moreover, the author thinks that primary tuberculosis of the mouth is not such a rare disease as is usually stated in textbooks. Many primary cases are taken for secondary affections; the clinical aspects of tuberculosis periostitis and osteomyelitis are very similar, in the bones of the mouth at least, to pyogenic periostitis and osteomyelitis.

Decayed teeth and septic mouths are commonly associated with mouth breathing and may be inciters of it. These conditions are insidious underminers of the natural resistance of the human organism by impairing the digestion and by the gradual production of a general toxemia. In tuberculosis, once it has gained foothold, the final outcome depends upon the integrity of the digestive system, and of the mouth and teeth in the first place. Those patients whose digestive disorders cannot be regulated are doomed from the start.

It seems axiomatic, from this standpoint alone, that life insurance medical examinations should take into consideration the condition of the mouth and teeth, and such examination should receive as much care as the lungs. Indeed, a septic mouth with carious teeth is of more importance as far as prognosis is concerned than a poor family history. No influence is more powerful in resisting disease than sound, clean teeth.—*Oral Hygiene,* May, 1912.

Occupation and Mortality.—Louis Jacquet has studied especially the mortality among dealers in alcoholic beverages. He has found that in all lands persons employed in this way show a mortality above the average. Thus, in Paris, the general mortality of men between 30 and 49 years old is 36.1 per thousand, while among saloonkeepers in the same ages it reaches 46.9. In Switzerland the general mortality at the same ages is 25.8 per thousand, while among saloonkeepers it is 42.59. Most instructive are the figures in England, although they are computed in a different manner. From these it is evident that there the general mortality has progressively diminished since 1880, while the death rate among saloonkeepers has just as progressively risen.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft,* Vol. XII, No. 3.

Accident Insurance of Students in Germany.—Möbius says that, with the exception of the Universities of Tübingen, Halle and Leipsic, the students in the German Universities are collectively insured against accidents, more than half of the universities being insured with one insurance company. In some universities the insurance is obligatory for all students, in others students of certain faculties may decide for themselves in taking advantage of it or not. Numerous officials of universities are likewise eligible, and in certain institutions not only the teaching force but all members of teachers' families over 18 years of age are protected. The insurance lasts from the beginning of one semester to the beginning of another; in two universities it is not in force during vacation time. Accident is defined just as is usual in such insurance contracts, but in certain instances special agreement is made including injuries and infections of medical and veterinary students resulting from the practical work in dissection, hospital work, etc., they are compelled to do.

So far as site of accident is concerned, all buildings under jurisdiction of the university are usually included. In certain instances, accidents anywhere during the semester are included. The indemnities agreed upon vary very much: death is indemnified by from 2000 to 5000 marks. Invalidism brings from 9000 to 25,000 marks. From 3 to 6 marks are granted for absence from work because of accident. Premium rates are usually very low, the lowest being half a mark for the semester; in some institutions students of medicine and chemistry pay higher rates than those in other faculties. However, the difference in the rates and in conditions of insurance in the different universities show that no scientific basis has been worked out, and Möbius suggests that this should be done in the near future. He thinks that the universities should unite and make a collective contract with accident insurance companies, so that uniformity of rates and indemnities may be attained.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft,* May, 1913.

Book Reviews.

Autobiography of a Baby. Told to Thomas Lindsley Bradford, M.D. New revised and enlarged edition. Price, 50 cents. Philadelphia: David McKay, 1912.

This little volume presents in an entertaining manner the main facts in nursery hygiene from the viewpoint of the baby himself. The comedies and tragedies of infant life are vividly portrayed. The pacifier, soothing syrups, etc., come in for their just share of condemnation, although some debatable questions, such as the causation of adenoids, are discussed as if there could be no difference of opinion about them.

Year Book of the United States Department of Agriculture, 1911. Washington: Government Printing Office, 1912. Octavo, 732 pages, numerous illustrations and full-page plates in black and colors.

The current Year Book of the Agricultural Department is of fully equal interest with recent numbers. The contents is, as usual, varied and interesting, the Report of the Secretary being followed by articles on Bird Reservations, Soils, Climate, Plant Pathology, Forrestry, Irrigation, Interesting or New Fruits, etc. A chapter is devoted to the new respiration calorimeter for use in the study of problems of vegetable life. The book concludes with the usual statistics of agricultural products. More space than usual is this year devoted to Insect Pests and the means of combating them.

The Key to Sex Control. The Cellular Determination of Sex and the Physiological Laws Which Govern Its Control. By Percy John McElrath, M.D. New York City: Published by the Author, 1911.

The present volume which is stated by the author to be the outcome of several years of study and experiment in the field of cell life, constitutes an interesting addition to the already extensive literature on this subject. Dr. McElrath states that his book is founded on the belief that the universe is governed by law and that the problems of heredity, sex, and development in the human species are based on infallible natural laws which may be studied and applied in a practical manner. It seems possible that sex may be predetermined in the lower animals, and breeders have made a practical application of this knowledge, but in the human species the sexual life is so differently constituted that any control, such as is proposed, will probably do very little to adjust the relative proportion of male and female children. As a basis for his conclusions, Dr. McElrath presents in a very complete and satisfactory manner the anatomy, physiology, and embryonic development of the generative organs and their functions. His descriptions contain some very novel deductions, particularly as regards the structure and behavior of the spermatozoa, which descriptions cannot be reproduced within the space of a brief review and for an understanding of which it is necessary therefore to refer to the book directly. An interesting point which he makes in relation to menstruation is that the rupture of the Graafian follicle does not normally occur until from five to sixteen days after the menstrual flow has ceased and that when the Graafian follicle is ruptured the ovum is normally propelled into the uterine cavity in six to eight hours. The time required for the ovum to reach the Fallopian tube after its extrusion from the Graafian follicle will always be problematical and subjected to variations in the same individual. Gravitation is claimed to be the only way to influence this, and a practical application of this knowledge consists in the direction given to a patient to lie on the side of that ovary from which the mature ovum is expelled, if this knowledge is possible. McElrath claims, moreover, that a Graafian follicle is not mature until it can be ruptured by orgasm in the female, and this period is not complete until from seven to fourteen days after the last day of the menstrual flow. An attempt has been made to explain the cellular basis of sex by a number of personal experiments in dogs and hens, which the author claims are sufficient to formulate rules for application to the human species. A number of statistical tables based on the author's personal observations in certain families are included for the purpose of confirming the author's theories along these lines, which it is necessary to consult in the original work. Dr. McElrath goes so far as to formulate a series of laws which govern the production of male and female offspring and even gives final instructions as to how a successful result in this direction may be accomplished. These results seem to depend on which day after menstruation insemination occurs and also on the character of the spermatozoa, whether young or old. He believes that young or recently formed spermatozoa are male producing and the older ones female producing. Whether it will be possible to disseminate a practical knowledge of these sex laws among the laity is questionable, although such a dissemination is in accord with the tendency of the present day, as regards a better knowledge of the physiology of the human organism by its possessor. Among the population at large, however, it would be a very difficult matter to control the relative proportion of the sexes, and we doubt very much whether among the highly organized members of our race it would even be advisable to have this matter under control, as the mental strain and uncertainty might have an effect, especially on the mind of the mother, which is far from desirable.

Practical Gynecology. A Comprehensive Text-Book for Students and Physicians. By E. E. Montgomery, M.D., LL.D., Professor of Gynecology, Jefferson Medical College; Gynecologist to the Jefferson Medical College and St. Joseph's Hospitals; Consulting Gynecologist to the Philadelphia Lying-In Charity, the Kensington Hospital for Women, and Consulting Surgeon to the Jewish Hospital. Fourth edition revised and rearranged. With five hundred and eighty-nine illustrations, the greater number of which have been drawn and engraved specially for this work, for the most part from original sources. Price $6.00 net. Philadelphia: P. Blakiston's Son & Co. 1912.

Three revisions of Professor Montgomery's text-book of gynecology have rapidly succeeded each other since the original publication in 1900, and in this, the fourth edition, the author has revised and rearranged the work so as to bring it up to date with progress in this subject. The author has attempted a very complete presentation of all that is important in gynecology, but it seems unfortunate that greater attention was not accorded to the arrangement of the subjects or greater care exercised in the proof reading. Many typographical errors are to be found scattered through the book, and in one instance two paragraphs are inserted in a description of chronic endometritis, which evidently belong to some other section. Mistakes in spelling are numerous and there are many incorrect terms, such as "diphtheric," which cannot be regarded as correct usage. Some question may also be interposed in regard to certain of the author's classifications, such as a division of tumors into genital and puerperal. A careful reading of the text fails to show what these and other distinctions are based on, particularly the puerperal group, in which physo-, hydro-, and pyometra are included with uterine cancer and mucus polyps. This is confusing to say the least. The book presents most of the accepted facts in gynecological pathology and therapeutics and the illustrations are generally well selected, but it would appear necessary to subject the book to a more careful revision before it can be regarded as more free from criticism than the present edition, which gives one an impression of being rather carelessly put together and incomplete.

Surgical Operations. A Handbook for Students and Practitioners. By Prof. Friedrich Pels-Leusden, Chief Surgeon to the University Surgical Clinic and Chief of the University Surgical Polyclinic in the Royal Charity Hospital of Berlin. Only authorized English translation by Faxton E. Gardner, M.D., New York. with six hundred and sixty-eight illustrations. Price $7.00. New York: Rebman Company. 1912.

Prof. Pels-Leusden has written here a very satisfactory work dealing largely with present day German surgical practice, and the completeness of the same is well shown from the study of any one chapter taken at random, such as that on anesthesia in the first part of the book, in which we are furnished with a detailed résumé of a great many more methods than are contained in the average surgical text book. The same may be said of the rest of the book's contents. After an introductory chapter on antisepsis and anesthesia, the book deals with the blood-vessels, the extremities, the head, the neck, the chest, the abdomen, and the urogenital organs. The book is well printed and bound and the illustrations, with the exception of some that have been borrowed from other sources, are well selected and generally satisfactory. We cannot, however, speak well of the English translation, which is not well done, and distracts the attention which the reader should be able to give to the subject matter of this work. Literal translations of German idioms, the frequent insertion of parenthetical clauses, numerous grammatical errors, and careless proof reading are among the faults most evident. If the English translation had been more carefully done, the book would deserve and would undoubtedly meet with a favorable reception.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Thirteenth Annual Meeting, Held at Montreal, Canada, May 31 and June 1, 1912.

DR. ALEXANDER D. BLACKADER IN THE CHAIR.

Friday, May 31—First Day.

Address of the President.—Dr. ALEXANDER D. BLACKADER of Montreal, stating that the society met this year under the auspices of McGill University, gave a sketch of the history of the city of Montreal and the founding of the university; after which he went on to say that, as given in its constitution, the object of the society was the promotion of therapeutics, a term which might be made to cover the whole of medicine, as well as surgery. Employing the term in the more limited meaning under which it was commonly understood, he had asked himself whether to-day therapeutics took the place it surely ought to hold in medical teaching and in advanced medical thought. To many it appeared to fail in doing so, and there were few of our great internists who had not for many decades been more or less permeated with "Osler's black, helpless, hopeless therapeutic pessimism." Personally, he could recall the comparatively numerous instances in which bleeding was recommended, the frequency with which mercury was pushed, in many inflammatory conditions, until the gums were touched, and the confidence with which tartar emetic was given in the early treatment of pneumonia, when he was a student of medicine in the sixties. He had a vivid recollection some years later of poring over the pages of his Ziemssen by night, reading the enthusiastic Liebermeister, and on the following day dosing his toxic typhoids with 20 or 30 grains of quinine, given two and three times daily, in the vain hope of lowering temperature and antagonizing the infection. Often he had sat up all night, at the crisis of a pneumonia, administering brandy with a free hand, and it was but yesterday that, to quote Osler, he had "plunged his sizzling hot typhoid patients into a bath of iced water for a quarter of an hour at a time, and watched them, all cyanosed, shiver and chatter in a vain attempt to regain at least comfort." Among the hundreds of drugs in our Pharmacopœias and Dispensatories, those which cured (our specific remedies) might be counted on the fingers—some would even say on the fingers of one hand. All the others assisted us only in the relief of symptoms, and too often, in this symptomatic treatment, the physician trusted to nature and played to the gallery. And, in trusting to this *vis medicatrix naturæ*, what a wonderful revelation of her powers in combating disease had been made to us by the studies of Metchnikoff, Ehrlich, Morgenroth, Wassermann, Wright, and many others. How dimly had we, up to the present, appreciated the fact that there resided within the animal body a set of potential forces capable, when aroused and stimulated, of exercising a highly effective control over almost all forms of disease. In the elucidation of these mysteries of nature the general practitioner had but a small place, for, as a rule, such investigations could be carried on only in institutions endowed by government, as in Germany, or by private individuals, of whom America afforded so many notable examples. Our belief was that in the strengthening of this wonderful mechanism of nature lay the therapy of the future, but there was still an infinity to be learned; for the mysteries of the antibodies had as yet scarcely been fringed. In connection with these thoughts we might recall that no advance in therapeutics had been of greater value to the world than the modern appreciation of the advantages arising from the breathing of fresh air; of sleeping in it, working in it, and, as far as possible, of living in the open. It was undoubtedly one of the greatest stimulants to the activities of the phagocytes and to the development of the various forms of antibodies which we to-day possessed. Doubtless, also, the great value of climatotherapy, hydrotherapy, psychopathy, and possibly of electrotherapy depended upon a similar stimulation of this defensive mechanism of nature. Bier's method of inducing local hyperemia, too, afforded the means for the reinforcement of these natural forces at any desired spot. Much valuable thought along these lines had likewise been given to the profession by our revered confrere, Dr. Sajous, who in his philosophical presentation of the adrenal, thyroid, and pituitary glands had told us of the active part which he believed they take in the development of antibodies. The profession all over the world placed a high estimate on the researches which his enthusiasm and unfagging energy had carried out in connection with the various activities of these internal secretions. Dr. Blackader was, however, by no means willing to be classed as a hopeless pessimist regarding the value of drug therapy. On the contrary, he had a strong belief in the limited value of the great majority of our pharmacopœal drugs when used with a definite knowledge of their action. Only when we knew the exact physiological action of a drug, both in health and under pathological conditions, were we able to use it in a useful, purposeful way and to avoid its undesired and too often toxic side-effects. The outlook in therapeutics had been dark because hitherto therapeutics had been taught as a mere empiricism. The future was bright because in all our best medical schools the students to-day were taught practically, as well as theoretically, the action of each drug; and it was his belief that if the many brilliant internists who were therapeutic pessimists had had the advantage of a practical training in a modern pharmacological laboratory during their student days, they would now be more optimistic, as well as clearer in their therapeutics. During the past year the cause of therapeutics had been greatly encouraged by the success attending Ehrlich's persevering investigations into the modifications of therapeutic action by variations in chemical structure. A similar investigation was now being carried on by Flexner, who was endeavoring to elaborate some modification of hexamethylenamine which, while retaining its central formation possessing an effective germicidal action, might develop a specific affinity for and a toxic action on the microörganisms of poliomyelitis. Owing to the growing demand of the profession for new agents, there had been forced upon its notice an enormous number of new drugs of whose action we had no knowledge except the statements of the commercial houses introducing them. He believed it was now generally recognized by thoughtful physicians throughout America that purely commercial interests had had too much to say during the last few years as to the composition and the nomenclature of many drugs now much used by reputable physicians. In the detection of the false and the uncovering of wrong the work done by the Council on Pharmacy and Chemistry of the American Medical Association had been of greatest value, and he desired to say how highly the profession in Canada appreciated the proposition of the council to institute a critical study of many of the more urgent problems in therapeutics which demanded investigation.

Obituaries.—Obituaries of the following deceased members were read: Carl Beck of New York, ex-president of the society, by Dr. Reynold Webb Wilcox; John H. Musser of Philadelphia, by M. Howard Fussell; Louis Nelson of Boston, by Dr. Clarence J. Blake; Henry A. Robbins of Washington, D. C., by Dr. J. W. Chappell.

Report of the Committee on Prize Competition in Therapeutic Research.—The Committee on Therapeutic Research reported that no report on a subject of therapeutic research had been received in the competition offered by the society, and recommended that the competition, instead of being confined to members of the American Therapeutic Society, should be thrown open to the profession at large; also that the amount of the prize offered should be increased from $200 to $300, or more. This report having been referred to the council, the council recommended that the prize should be $500 and that the competition should be open to the medical profession of the United States and Canada, and these recommendations were afterwards approved by the society.

Some Common Types of Hyposecretion of the Thyroid.—Dr. OLIVER T. OSBORN of New Haven, Conn., said the object of his paper was to present a few types of cases which he considered to be due to subthyroid secretion. Unquestionably, many of these patients were psychopathic, and might improve under mental treatment. The thyroid was peculiarly susceptible to mental stimulation and to mental depression, and anything which quieted mental excitation would diminish a hypersecretion of the gland, while anything which removed mental depression would increase a subnormal secretion of the gland. Some cases of disturbed thyroid secretion looked like pure hysteria, and hence many would be inclined to ascribe the favorable results obtained by treatment directed to the thyroid as simple instances of mental impression. As this gland had a good deal to do with the condition of the blood, when it was subsecreting it would sometimes allow a condition of this to occur which was not dissimilar to that of hemophilia; in other words, a very aplastic condition, perhaps with a diminished calcium content. When we recognized the very important part the thyroid played in the life of the female, it was not to be wondered at that the gland was

apt to become overworked and that it should finally hypofunctionate. The conditions for which, in his opinion, thyroid subsecretion might be responsible were, cretinism, some forms of eczema, some forms of asthma, infantile obesity, adiposis dolorosa, lipomatosis, some digestive disturbances, some forms of melancholia, chlorosis, amenorrhea, myxedema, senility, and perhaps Raynaud's disease. The stimulants to thyroid secretion were great sorrow great joy, nervous tension, sexual excitement, genital disturbances (especially uterine), pregnancy, cerebral stimulants such as coffee, tea, and alcohol, and such drugs as arsenic, iodides, phosphorus, salicylic acid, pilocarpine, and, of course, thyroid extract. The speaker gave reports of a number of cases illustrating the various conditions due to thyroid hyposecretion and the benefit derived from the administration of thyroid extract, and, in conclusion, urged that, when thyroid was needed, but small doses be used, as it was an agent potent for harm. When given to patients who ought not to receive it, it would make their symptoms worse, and sometimes but a little of it would push a wavering thyroid gland to hypersecretion and Graves' disease. Much of the thyroid substance on the market was inactive, but a small amount of coincidentally administered iodine, as an iodide, would render it active.

Dr. Francis M. Pottenger of Los Angeles, Cal., mentioned a case illustrating the value of recognizing the existence of abnormal thyroid secretion; that of a young married woman whose condition was similar to that of one of Dr. Osborne's cases. She was sleepy, listless, sluggish, and forgetful of her children and her household duties, and had, indeed, become so degenerate that her husband left her. Having been led to consider thyroid hyposecretion as the possible cause of trouble, the speaker gave her thyroid extract, and the result was that, in the language of her family, she was "made over."

Notes on the Differentiation of Cardiac Arrhythmias and Their Treatment, with a New Time Marker.—Dr. Thomas E. Satterthwaite of New York said that the subject of cardiac arrhythmias took on a new phase as soon as graphic methods were used for their differentiation, and most of the discoveries due to them, amounting practically to a revolutionizing of the whole matter, had been the work of the last ten years. It had now been generally accepted that arrhythmias might be satisfactorily classified with reference to the five physiological attributes of heart muscle demonstrated by Gaskell in 1882; rhythmicity, irritability or excitability, contractility, conductivity, and tonicity. Corresponding to the first four of these, there were four distinct varieties of arrhythmias capable of being demonstrated by graphic tracings. To the first of the varieties he had given the name of pneumogastric arrhythmia, because of its close relation to pneumogastric influences, and it was a variation from the standard cycle within physiological limits. In the second variety, the extrasystolic there were extra, or supernumerary, contractions, from stimuli not originating in the sinus venosus like the pneumogastric arrhythmia, though in the main the regular or sinus rhythm was maintained. There were two principal types, the ventricular and the auricular. All extrasystoles were followed by a pulse period rather longer than the normal. The really most important function of heart muscle was contractility, and a striking example of its abnormal characteristics was seen in the alternating pulse, in which the alternation of large and small beats was continuous, thus distinguishing it from extrasystolic arrhythmias. Another variety of abnormal contractility was seen in auricular fibrillation, where the cardiac cycles varied so much that there was no sequence of beats having the same length. This was responsible for most of the disturbances of the ventricular system. Indeed, in the vast majority of instances a sphygmogram showing that no two successive beats were of the same length meant the diagnosis of auriclular fibrillation. In affections of conductivity the normal stimulus, which started in the sinus and passed over the bridge of His to the ventricle, might be delayed in its course, might not cross at all, or might be arrested beyond the bridge; any one of which conditions might produce heart block. The pulsus infrequens, improperly called the slow pulse, almost always indicated a loss of conductivity. Disturbed rhythmicity, the first of the types of irregularity, did not as a rule warrant us in sounding notes of alarm, as it was really physiological. In extrasystole there might be a neurotic base, or it might result from the pressure of gas from gastrointestinal fermentation; or, again, it might be a reflex from the alimentary canal, as in indicanuria. In the one case, sedatives, such as camphor and bromides, were useful; in the latter, remedies regulating gastric or intestinal digestion. If the extrasystoles were due to overuse of coffee, tea, or tobacco, the indications were evident. In auricular fibrillation no remedy was so satisfactory as digitalis or its congeners, of which strophanthus was the best. Acute heart block might be due to digitalis, in which case the drug should of course be at once discontinued. If syphilis were present, antisyphilitic treatment should be pushed. Atropine, 1/60 grain, was available as a test to determine whether the heart block was due to a lesion of the pneumogastric.

On account of the expensiveness of the Jacquet time marker, Dr. Satterthwaite had devised an American time marker, which could be made at home and involved no great expense. No large institution, he said, ought to be without a good polygraph.

The Relation between High Blood-Pressure and the Adrenals.—The symposium was opened by Dr. Charles E. DeM. Sajous of Philadelphia, with a paper on this subject. The functional relationship, he said, between the adrenals and the blood-pressure, through the direct action of their secretion upon the muscle fibers of the heart and arteries, as well as the fact that the arterioles received the brunt of the contractile action of the secretion, was now well established. On account of the limited time at his disposal, he could treat of but one of the morbid effects which this action of the adrenal product might entail, arteriosclerosis. That the production of vascular lesions resembling at least those of arteriosclerosis was caused by injections of adrenalin had been attested by many observers. Some of these, it was true, had argued that the lesions differed from typical arteriosclerosis, but when we reflected that syphilis was one of the important etiological factors in arteriosclerosis, it seemed clear that this view was not well founded. Having referred to other objections, he said that McConnell had stated very recently that the changes which developed did not correspond accurately with those of the ordinary nodose sclerosis, but they were indistinguishable from the changes seen in Moenckeburg's type of medial degeneration. The statistics as to causation of 6,129 cases of arteriosclerosis in various parts of the world suggested a toxemia as the common pathogenic factor of the condition—specific toxins where infectious diseases were the causative agents; excessive metabolism and tissue waste products in hard physical labor; purin bases in gouty cases, as well as those due to chronic lead poisoning. All these main causes of arteriosclerosis could thus be summarized by the one word, intoxication, as long ago emphasized by Traube and Rokitansky. As to the relationship between this general toxemia and the adrenals, it was a fact that all but one (alcoholism, which had not been studied in this connection) of the morbid conditions known to provoke arteriosclerosis had also been known to cause overactivity of the adrenals. He cited authorities in reference to these several conditions, and said that this evidence was further sustained by the fact that Coplin, in an examination of the adrenals of 22 cases of arteriosclerosis, found that 17 were markedly altered, the exceptions being the seat of a tuberculous process in three instances and of a secondary neoplasm in one. Again, potassium iodide, our best remedy in arteriosclerosis, had been found to inhibit the secretory activity of the adrenals. We were thus brought to attribute to adrenal activity the production of clinical arteriosclerosis, a process similar to that caused by Josué when he injected adrenalin experimentally. Now, whether we injected adrenalin or whether the adrenals were overactive, what effects were produced on the vascular system *per se* were borne directly by the terminal arteries. This appeared to the speaker to furnish the key to the situation, or, rather, the missing link of a chain of facts which clearly explained the pathogenesis of at least the familiar forms of arteriosclerosis from beginning to end. Briefly, the pathogenic toxic agent, whatever it happened to be, caused more or less violent overactivity of the adrenals (probably by exciting their center), and thus increased their secretory activity sufficiently to reduce more or less the caliber of the arterioles from which the vasa vasorum received their supply. Deficiently nourished through these, their nutrient vessels, the medial and intimal vascular tissues degenerated, forming the familiar sclerotic patches.

The Nature of the Cardiovascular Changes in Nephritis.—Dr. Alfred C. Crofton of Chicago said that in attempting to interpret the cardiovascular changes occurring together with nephritis it was important to remember that, on the one hand, many cases of nephritis ran their whole course without the appearance of any cardiovascular manifestations whatsover, while, on the other, cases of nephritis sometimes occurred in which increased blood tension made its appearance within forty-eight hours after the onset of the renal difficulty and rapidly led to organic cardiac and arterial lesions which proceeded

throughout the course of the disease. The first part of the paper was devoted to a consideration of those forms of cardiovascular degeneration occurring consecutively to nephritis. Of the large number of cardiovascular disorders in which blood-pressure changes either precede or accompany nephritis one could logically distinguish three possibilities: 1. The cardiovascular changes preceded and caused the nephritis. This, he believed, was the sequence of events in true Bright's disease, for in many of the cases of this we saw high tension long before nephritic symptoms appeared. A persistent increase in the arterial pressure ultimately led to degenerative changes, particularly in organs of the body supplied by end arteries, and chiefly the kidneys, the retina and the brain. 2. The cardiovascular changes developed simultaneously with the nephritis. Here some agency must be operative which affected both the cardiovascular apparatus and the kidneys, and to this category belonged chiefly the cardiorenal disorders seen in chronic lead poisoning and, above all, in the so-called gouty diathesis. 3. The cardiovascular changes were manifestly of renal origin, consecutive to the nephritis, and in all probability due to renal inadequacy with retention of urinary end products. It would consequently be seen how important it was from the standpoint of prognosis and treatment to attempt in each case of nephritis complicated with cardiovascular disorders an interpretation of the sequence of events.

High Blood-Pressure Arising from Nervous Strain in Diseases of the Nervous System.—Dr. BLACKADER read a paper by Dr. EDWARD D. FISHER of New York, on this subject. In looking at the subject from his special standpoint, the author said, he would emphasize the fact that many of those conditions already discussed were present and complicated the special disorders of the nervous system—in fact, might be the real cause of the trouble. He would call attention particularly to diseases of the nervous system due to arterial disease, either endarteritis of the atheromatous type or that consequent upon syphilis, to cerebral compression as caused by new growths, increase of cerebrospinal fluid, etc., and to vascular changes due to direct poisons, such as uremia, diabetes, alcohol, etc. In the first group, endarteritis of a degenerative type, a rather general distribution of arterial disease was found; so that, not only was the nervous system involved, showing cerebral and spinal symptoms, but interstitial nephritis and cardiac hypertrophy were also present. In cases under forty, with probably acute cardiac and kidney involvement, we had symptoms peculiar to disorders of the special organs, but no, or only slight, tendency to cerebral hemorrhage or epilepsy, as in older persons. In them the blood-pressure might be temporarily high, but was not continuously so, and was more easily relieved or controlled; while in cases over forty there was a constant high blood-pressure, subject also to marked increase—which was the danger point indicating the probability of a seizure, apoplectic or epileptic. The arterial condition here marked out positively the difference between such epileptic seizures and so-called idiopathic epilepsy, and also that due to a focal lesion. In eclampsia during pregnancy a great and often sudden rise in blood-pressure previous to the seizure was frequently observed, and this was evidently not due to arterial disease, but to some toxic agent in the blood. High blood-pressure when occurring during pregnancy should be regarded as a danger signal. If in syphilitic endarteritis the blood-pressure, contrary to the usual rule, were high, this was to be explained, not by the arterial disease, but by complications; which probably explained the clinical condition, due, as a rule, not to cerebral hemorrhage, but to cerebral thrombosis. In such cases there was a cerebral anemia resulting from a gradual occlusion of the caliber of the vessels by actual thickening of their coats, or actual infiltration of new growth into their walls. Other complications might, however, modify this picture, explainable, as in non-specific cases, as due to exogenous or endogenous causes. In cerebral growths we found cerebral compression, which might also manifest itself by high blood-pressure, permanent or continuous. Here again we found there were variations dependent upon exciting conditions, such as cephalalgia, disease of the kidneys or heart, drugs, etc. The convulsions present might be due to anemia from pressure. High blood-pressure in cerebral tumors, in hydrocephalus, or in compression following trauma might be observed to fall as soon as the skull was opened, or, more surely, on opening the dura, with the escape of cerebrospinal fluid. This was not always the case, however, in decompression operations for traumatism; many such cases continuing to show high blood-pressure and failing to regain consciousness. During cerebral operations taking the blood-pressure was valuable as a routine, as rapid fall indicated the need of stimulation or cessation from further operating at the time. In closing, Dr. Fisher emphasized the great value ot observing the blood-pressure in all cases of vascular disease; stating that its sudden or steady rise indicated the line of treatment, which might avert a catastrophe. At least, it might inform us of the danger of our patient.

High Blood-Pressure in the Toxemia of Pregnancy.—Dr. D. J. EVANS of Montreal said that in 12 of a series of 38 cases of pregnancy complicated with eclampsia, albuminuria, or vomiting of a toxic type which he had recorded the toxic condition was severe enough to call for the interruption of the pregnancy. In 8 cases eclamptic convulsions occurred, and among these the highest blood-pressure noted was 200 mm., and the lowest, 140 mm. In most instances the blood-pressure immediately before the convulsions was between 170 and 190 mm. One of the patients had three convulsions, though her blood-pressure never rose above 150 except just at the time of the convulsion. Two had a blood-pressure of 200, one with 5 and the other with 18 convulsions, and the child of the former died of convulsions 14 hours after spontaneous delivery. There were 4 cases of severe vomiting: 2 early in pregnancy and 2 near term. In the latter the blood-pressure was 140 in one and 125 in the other, and in both these labor was natural and the children were born alive. In the former, one whose blood-pressure was never above 125 recovered from her vomiting and went to term, while the other, a most severe case, was aborted at the sixteenth week and died 10 days later. For a considerable period the blood-pressure of this patient was taken several times weekly, and was usually found to be about 100 (never above 110); yet she developed retinal hemorrhages and other signs of severe toxemia. The other 26 cases were all albuminurics, with toxic symptoms of more or less severity. Seven of these had a blood-pressure of 160 or over—2 of them recording as high as 180—and in 12 it was 140 or under, the lowest record being 120. As the result of his experience he was inclined to conclude that the blood-pressure record is of little value as indicating the degree of toxemia present in cases of vomiting in pregnancy. Moreover, he had been surprised at the comparatively low reading obtained in many cases where the symptoms indicated the existence of a very considerable degree of toxemia. In three instances induction of labor was imperative, though the blood-pressure was 150 or under, and in four with a blood-pressure of over 150 the toxic symptoms were so slight that the cases were permitted to go to term, when they were delivered naturally. He was inclined to consider 160 as the danger limit, and that in cases where, in spite of treatment, the toxic symptoms do not yield and the blood-pressure is maintained as high as this point, or higher, labor should be induced. In cases of pregnancy with high blood-pressure without toxic symptoms there was little occasion for anxiety. In all cases with hepatic or renal insufficiency the blood-pressure should be carefully watched. A rising blood-pressure in such cases, associated with other toxic symptoms, was indicative of danger, and here he would consider 160 mm. of pressure the danger limit.

Factors Which Alter Blood-Pressure in Pulmonary Tuberculosis.—Dr. FRANCIS M. POTTENGER of Los Angeles, Cal., said that in a former paper he had drawn the following conclusions regarding blood-pressure in this disease: 1. A relatively low pressure is found in tuberculosis, especially in advanced tuberculosis. 2. The factors which favor low pressure are the effect of the toxins upon the vasodilators, the weakness of the heart muscle, and general wasting. 3. The factors which have a tendency to maintain pressure are hypertrophy of the heart muscle and thickening of the systemic arteries. 4 Thickening of the systemic arteries occurred perhaps as a result of the action of the toxins on the vessel wall, and was, therefore, found especially in those who had had tuberculosis for some time. Further experience had confirmed his former observations and also enabled him to add one more factor which he believed was of great importance in causing low pressure, namely, the altered function of the diaphragm and its accompanying splanchnic congestion and relative arterial anemia. It was well known that the splanchnics were capable of holding nearly all the blood of the body: therefore, if the splanchnics contained more than their normal amount of blood it was self-evident that the arterial system must suffer a deficiency, with a resultant low tension. His own theory as to the altered function of the diaphragm, due to displacement and diminished action, was that it is a part of the general scheme of protection by lessened motion, such as has long been recognized in abdominal lesions, and that its cause was the same as that which produced the spasm of the muscles of the neck and chest under the

same conditions; a reflex stimulation, the impulse passing from the inflamed lung to the cord, and there stimulating the adjacent cells of the segment and sending out stimuli to the diaphragm, through the motor fibers which took their origin from contiguous cells, causing the diaphragmatic muscle to assume a condition of tonic contraction or spasm.

The General Treatment of High Blood-Pressure.—Dr. SPENCER L. DAWES of Albany, N. Y., said the general treatment would naturally include the treatment by manual methods, regulated movements, baths, electricity, and sodium nitrite, but as papers on these were announced in the symposium, they would not be considered under this head. General treatment might be divided into (1) prophylactic, (2) curative, and (3) symptomatic. (1) A regulation of the habit of the individual as to diet, exercise, and excretion included the prophylactic measures indicated. Modern, rational, and, above all, systematic exercise would do more to prevent sclerosis of the arteries and its accompanying hypertension even than a regulation of the diet. And, in addition to this, most active business men should obtain at intervals, certainly once a year, the relaxation attendant upon a sea voyage or a period in the actual country, away from the excitement of business and society. (2) Here we should pay our first attention to causation, such as gout, syphilis, the excessive use of alcohol, and overindulgence of all kinds, for, after all, it had to be admitted that high blood-pressure was a symptom, rather than a disease. By far the most popular of all drugs used with the idea of cure was iodine in some form, given oftentimes to the point of toleration; but its value rested more upon empirical evidence than upon accurate measurement of the blood-pressure. Having discussed the administration of iodides, he passed on to the third point, symptomatic treatment. Unfortunately, he said, most of our efforts had to be directed toward relief, since the majority of patients did not come to us until a distinct arteriosclerosis was established, when it was often impossible to benefit them by curative treatment. Venesection, which had been abandoned on account of its abuse, not infrequently gave brilliant results in appropriate cases. Again, results as gratifying to the physician as to the patient might attend upon the free use of calomel or the mass of mercury, followed by a brisk saline purge. When there was intestinal torpor, with decomposition of the animal food, lactic acid tablets might be employed to advantage. In certain types of cases where there were inefficiency of the skin and kidneys and myocardial degeneration, with or without valvular disease, the promotion of free diuresis was often of great help; and here digitalis was of greatest value, notwithstanding that primarily it increased the arterial tension. Theobromine sodiosalicylate was also helpful, as, in addition to its action on the kidneys, it had a direct effect upon the vasomotor center and secondarily upon the blood-pressure; and the combination of these two remedies at times gave remarkably good results. For immediate effect upon hypertension, as well as for continued use over a long period, no class of drugs equaled the nitrites. Care should be taken, however, not to lower the blood-pressure to a point where the secreting function of the kidneys was unfavorably affected, and it was also well always to remember that not all cases where there was high blood-pressure demanded, or even admitted, a reduction of the tension, for as long as the cardiac powers compensated for obstruction in the circulation, no special treatment was needed.

Treatment by Mind Control and Mechanical Agencies Making for Vasomotor Control.—Dr. J. MADISON TAYLOR of Philadelphia said that since there was still so much doubt as to the gravity of the symptom, vascular hypertension, indecision as to how far it was an evidence of organic conservation, it was the part of wisdom to employ in overcoming it only those vasorelaxing agents whose action was understood, capable of exact regulation and likely to do the least harm. Many drugs were admittedly capable of confusing, even dangerous, retroaction; hence, in the absence of a precise knowledge of the action of these medicaments and a full appreciation of the complex factors present, there might be recommended training in mind control and simple, trustworthy mechanical and thermal agencies capable of opening or closing the blood-paths. A large number of individuals exhibited psychic hypertension as a common feature of various other derangements; also a vascular hypertension of from 10 to 25 mm. Hg. Again, it was a common observation that where conditions for vascular hypertension existed there was also psychic hypertension. In the case of the former marked relief was afforded by applying well-chosen methods of psychic relaxation; in the latter, no matter what the underlying cause, a gratifying and increasing lowering of vascular tension was occasioned by securing mental relaxation. Persistence in training in mind control produced satisfactory and permanent vascular relaxation and relief of distressing sensory symptoms. Having outlined his methods, which he said were more fully set forth in a paper entitled "Psychic Hypertension" in the *International Clinics* for July, 1912, Dr. Taylor stated that the following were satisfactory mechanical measures inducing vasomotor relaxation: (1) Manual therapy—using the fingers to press gently and continuously (distributed pressures) on the paravertebral tissues; useful in both acute febrile and protracted states. (2) Skin friction of the whole surface, dry or with water, for periods of not less than 20 to 30 minutes, preferably twice daily; especially for protracted or chronic vascular excitation. (3) Gentle, systematic, increasing passive, active, and resistant movements, watching the heart; also steady walking, slow "trudging" on level or gently sloping ground (*e.g.* "terrain kur" of Carlsbad, Aix, etc.). (4) Baths, especially the "neutral immersion bath"—water at 92° to 98° F., preferably containing sodium and calcium chlorides, in which the patient lay for half an hour to two hours once or twice daily.

Treatment by the High Frequency Current.—Dr. HOWARD VAN RENSSELAER of Albany, N. Y., said that in medicine it was customary to use a current in which the cycles ran from 200,000 to 2,000,000 per second, and with the high voltage of 10,000 to 500,000 volts. Both frequencies and voltages much in excess of these limits might be passed freely through the body, but when given much higher than these they gradually lost their therapeutic properties. Just what were the most advantageous frequency and voltage for the effect on the human system had not as yet been scientifically demonstrated. In its passage through the body the high frequency current seemed to contract or modify the vibrations of individual cells everywhere in such a way that it stimulated abnormally vibrating cells, bringing them back to their normal vibrations and thus restoring their health and function, as well as stimulating healthy cells to increased action. Its action was thus physiological, and the fundamental value of this form of electricity seemed to lie in its power of regulating and stimulating all nutritive processes. If the blood-pressure of a person with hypertension were taken before the electrical treatment, and again directly afterward, it would be found to have fallen, and, in general, the higher the tension the greater the fall, provided that arteriosclerosis were not present. The first treatments might not keep the blood-pressure down for twenty-four hours, but each succeeding day, if the electricity were given daily, the tension stayed lower for a longer time. Usually it stayed down longer than twenty-four hours within a fortnight, and after that the interval between the treatments might be gradually lengthened to once a week, or even once a fortnight. The action of the electricity appeared to be to modify and improve the underlying processes causing the high blood-pressure. The speaker related a case illustrating the good effects of the high frequency current on a person in the earliest stage of Bright's disease, before renal symptoms had been demonstrated, and expressed the opinion that had this patient not taken the electrical treatment the intestinal toxins present would in a few months, or a few years at the most, have produced a condition of hopeless chronic Bright's. From his study of this subject he offered the following premises and deductions: *Premises.*—(1) The underlying cause of most cases of high blood-pressure is metabolic, from faulty digestion of food. (2) The hypertension usually precedes renal, cardiac, and arteriosclerotic changes. *Deductions.*—That by proper treatment with high frequency currents (1) the general condition is improved, and especially the metabolic processes, so that less toxins are formed and absorbed; (2) when, by the aid of the sphygmomanometer, hypertension is recognized early, we are able to cure the initial stages of the disease, because we remove the exciting cause; (3) that we can prevent the actual dvelopment of Bright's disease; (4) when renal or cardiac lesions are already present, that we can check the rapid advancement of the pathological processes and thus prolong life; (5) in the later stages of the disease, when compensation has broken and the heart has begun to fail, that by lowering the tension we lessen the resistance which the enfeebled heart is obliged to overcome, and so can alleviate some of the symptoms and make the patient more comfortable; (6) that by the effect of the current in lowering arterial tension we protect the brittle blood-vessels from the liability to rupture, and thus we can minimize the danger of apoplexy.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

July, 1911.

ANATOMY.

1. Give the relation of the internal abdominal ring to surrounding blood-vessels.
2. Give the origin, principal branches, and distribution of the superior mesenteric artery.
3. Give the boundaries and contents of the axillary space.
4. What part of the brain is most freely supplied with blood?
5. Describe the blood supply to the liver structure.
6. Describe the large intestine and tell how it differs from the small intestine in structural arrangement.
7. Give the names of the (*a*) temporary teeth in their order from front to back, (*b*) permanent teeth in same order.
8. What nerves unite to form the brachial plexus?
9. Name the most important nerve branch of the cervical plexus, its point of origin, and its distribution.
10. Give the names and locations of the bones of the face.

PHYSIOLOGY.

1. (*a*) What is meant by digestion? (*b*) Describe the process of digestion of an egg sandwich.
2. Discuss the factors concerned in venous circulation.
3. (*a*) Describe a cell. (*b*) How are cells propagated? (*c*) Give the functions of nerve cells.
4. (*a*) Describe the vasomotor system. (*b*) Give its function. (*c*) What center controls it?
5. (*a*) Compare voluntary and involuntary muscle. (*b*) What is muscular coordination? (*c*) By what centers is it controlled? (*d*) What causes muscular fatigue?
6. (*a*) Describe the respiratory function. (*b*) What is meant by the terms: (1) Residual air? (2) Vital capacity?
7. (*a*) Give the composition of the blood. (*b*) Reaction. (*c*) Specific gravity. (*d*) Amount in the body. (*e*) Time required for a complete circulation.

MATERIA MEDICA AND THERAPEUTICS.

1. Define solvent. Mention three principal solvents.
2. Define diaphoresis. Mention three diaphoretics and state the dose of each.
3. State the name and the dose of each of two cardiac stimulants.
4. In what form is iodine most frequently administered internally? What is the antidote for free iodine?
5. What serious results may ensue from the indiscriminate use of acetanilid?
6. Mention the conditions which affect the dosage of medicines.
7. What is cumulative action? Name one drug that has this tendency, and give symptoms of such action.
8. Name and describe three antiseptics useful for internal medication.
9. Name three indications for the use of opium.
10. How and when would you perform hypodermoclysis?

CHEMISTRY.

1. Give the formula for the two chief products of yeast fermentation of sugar and state the differences, if any, in the action of yeast upon cane sugar, milk sugar, and grape sugar.
2. State the chief differences between fixed and volatile oil and name three of each class that are extensively used in medicine.
3. Give the chemical composition and properties of ammonia gas.
4. Give the approximate constituents of cow's milk.
5. Give the chemical formula for urea and what is the normal amount excreted daily by an average adult.

PHYSICAL DIAGNOSIS.

1. Give physical signs of aneurysm of the thoracic aorta.
2. Give cardinal symptoms by which you can diagnose a case of appendicitis.
3. Give topographical anatomy of the heart and its valves.
4. (*a*) Give normal temperature of the body. (*b*) Give normal pulse (frequency).
5. If a man or woman, past middle age, complaining of constant slight vertigo, intensified on excitement or exertion, presents sclerosed arteries, arcus senilis, and ringing aortic closure, with or without moderate cardiac hypertrophy, what would be your diagnosis?

PATHOLOGY AND BACTERIOLOGY.

1. Define in contrast infection and intoxication.
2. What do you understand by phagocytosis, and what is its relation to immunization?
3. From what does thrombosis of the portal vein most frequently result?
4. From what does chronic gastritis most frequently result?
5. Name the pathological conditions most commonly found in the lymphatic glands.
6. How would you demonstrate the presence of the amœba coli in a case of amœbic dysentery?
7. How would you demonstrate the efficiency of a germicide?
8. Describe one method by which you can demonstrate the agglutination of bacteria by blood serum.
9. What bacteria most frequently cause puerperal infection?
10. Examine and name the pathogenic organisms under the microscopes No. 1, No. 2, No. 3.

ETIOLOGY AND HYGIENE.

1. Give the accredited causes of malaria and yellow fever and tell what measures afford the best means of protection from infection.
2. How are impurities in water classified; how can they be detected, and why is the presence of organic material in drinking water deleterious?
3. Illustrate the theory of immunity by means of antitoxin.
4. Is infantile paralysis infectious? If so, give rules for protecting the community.
5. Give etiology of: (*a*) hepatic abscess, (*b*) cardiac hypertrophy, (*c*) edema of the lungs.

PRACTICE.

1. Write in parallel columns the diagnostic symptoms of measles and smallpox.
2. Write in parallel columns the diagnostic symptoms of neuralgia and myalgia.
3. Mention the forms of insanity, and give the most common causes.
4. Give a differential diagnosis of pleurisy and pneumonia.
5. What are the average durations of the febrile stages in the following forms of disease: Typhoid fever, scarlet fever, measles, rheumatic fever, and pneumonia?
6. Give the symptoms of greatest diagnostic importance in locomotor ataxia.
7. Give the pathognomonic symptoms of hysteria.
8. Give symptoms and treatment of incipient phthisis.
9. What forms of disease present symptoms during the first three days resembling variola?
10. With what form of disease may scarlatina be confounded prior to the appearance of eruption?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

July, 1911.

ANATOMY.

1. *Relation of internal abdominal ring to surrounding blood-vessels:* The external iliac artery and vein lie immediately under the ring; the deep epigastric vessels are internal to the ring; and the deep circumflex iliac artery is external to the ring.

2. SUPERIOR MESENTERIC ARTERY. *Origin:* Abdominal aorta. *Branches:* Inferior pancreatico-duodenal, vasa intestini tenuis, Ileo-colic, Right colic, and Middle colic. *Distribution:* All the small intestine, except the first part of the duodenum; cecum; ascending and transverse colon.

3. The axilla is *bounded: Anteriorly,* by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly,* by the Subscapularis, Teres major, and Latissimus dorsi; *internally,* by the first four ribs, first three Intercostal muscles, Serratus magnus; *externally,* by the humerus, Coracobrachialis, and Biceps.

Contents: Axillary vessels; brachial plexus of nerves and their branches; some branches of the intercostal nerves; lymphatic glands, fat, and loose areolar tissue.

4. The gray matter and the base of the brain are most freely supplied with blood.

5. The substance of the liver derives its blood-supply

from the hepatic artery and its branches, also from the small hepatic branch of the gastric artery.

6. The large intestine extends from the termination of the ileum to the rectum. It differs from the small intestine in: (1) Its larger size; (2) its more fixed position; (3) the possession of teniæ; (4) in being sacculated; and (5) in possessing appendices epiploicæ.

The colon is divided into ascending, transverse descending, iliac, and pelvic. The *ascending colon* extends from the cecum to the under surface of the liver to the right of the gall-bladder, where it turns to the left, forming the *hepatic flexure*. It lies in the right iliac and right hypochondriac regions. The peritoneum covers the anterior and lateral surfaces. Length, 8 inches. The *transverse colon* passes from right to left, from the gall-bladder to the spleen. It forms an arch, convex anteriorly and below: the *transverse arch of the colon*. It is entirely surrounded by peritoneum, which is attached posteriorly to the spine, forming the mesocolon. Length, 20 inches. The *descending colon* passes from the end of the transverse colon by a bend, *the splenic flexure*. Between the splenic flexure and the diaphragm, opposite the tenth left rib, is a fold of the peritoneum, the *costocolic ligament*, which slings up the spleen. The gut then passes downward to the iliac crest, ending in the iliac colon. The peritoneum invests its anterior and lateral surfaces. Length, 4 to 6 inches. The *iliac* colon is continuous with the descending colon at the left iliac, crest, and ends at the inner border of the left psoas. Peritoneum invests its anterior and lateral surfaces; it has no mesentery. Length, 5 to 6 inches. The *pelvic colon* extends from the inner border of the psoas to the level of the third sacral vertebra. Length, 16 or 17 inches; very variable. It has an extensive mesentery.—(From *Aids to Anatomy.*)

7. The *temporary* teeth, from front to back, are: Central incisor, lateral incisor, canine, first molar, and second molar.

The *permanent* teeth, from front to back, are: Central incisor, lateral incisor, canine, first bicuspid, second bicuspid, first molar, second molar, and third molar.

8. The brachial plexus is formed by the union of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves.

9. The most important nerve branch of the cervical plexus is, probably, the phrenic nerve. It arises chiefly from the fourth cervical nerve, with filaments from the third and fifth cervical nerves. It is distributed to the diaphragm, pericardium, and pleura.

10. THE BONES OF THE FACE. Two *nasal*, forming the bridge of the nose. Two *superior maxillary*, forming upper jaw; part of roof of mouth, nasal fossæ and orbital cavities. Two *lachrymal*, situated at the front and inner part of the orbit. Two *malar*, at upper and outer part of face, forming the cheek bone. Two *palate*, at back part of nasal fossæ; they assist in formation of roof of mouth, and floor of orbit. Two *inferior turbinated*, on outer wall of nasal fossæ. *Vomer*, forming septum of nose. *Inferior maxillary*, or lower jaw.

PHYSIOLOGY.

1. *Digestion* is the name given to the series of changes occurring in food from the time of its ingestion till it is ready for absorption.

An egg sandwich consists of bread (proteid, carbohydrates and fat), butter (fat), and egg (proteid and fat).

The proteid is digested in the stomach and small intestine, where the pepsin (of the gastric juice) and trypsin (the pancreatic juice), respectively, turn it into proteoses and peptones. The carbohydrates are digested in the mouth, and small intestine, where the ptyalin (of the saliva) and amylopsin (of the pancreatic juice), respectively, turn it into maltose and dextrose. The fat is digested in the small intestine, where it is saponified by the steapsin (of the pancreatic juice) and the bile.

2. The factors concerned in venous circulation are: (1) The force exerted by the heart; (2) the suction action of the chest during inspiration; (3) the voluntary muscles; (4) the valves in the veins.

3. A *cell* is a mass of protoplasm, with a nucleus, and sometimes a nucleolus, centrosome, attraction cell and cell-membrane. It is capable of movement, response to stimuli, ingestion, egestion, assimilation, and reproduction. Cells multiply by simple division, but the division of the protoplasm is preceded by division of the nucleus. This latter occurs in two ways: (1) By direct, or simple, or amitotic division; and (2) by karyokinesis or indirect division, the more common way.

The *functions of nerve cells* are: (1) Receiving nerve impulses; (2) sending out nerve impulses; (3) modification of nerve impulses; and (4) nutrition of itself and its dendrites and axon.

4. "The vasomotor system may be said to be composed of the vasomotor center, situated in the medulla, together with some accessory and subsidiary centers in the spinal cord, and vasomotor nerves. The nerves are divided into two classes, according as they increase or diminish the calibre of the arterioles; those which increase the caliber are vaso-dilators; those which diminish the same are known as vaso-constrictors. All nerves that in any way influence vessel caliber are classed under the general head of vasomotor." (Ott's *Physiology.*)

5. *Voluntary muscle* is more or less under the control of the will; *involuntary* muscle is not under the control of the will, it is rhythmical in its contractions, and is also characterized by peristalsis.

Further, *voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is non-striated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated. *Voluntary muscle* is found in all the skeletal muscles, pharynx, diaphragm, larynx, external ear, and eye. *Involuntary muscle* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

By *muscular co-ordination* is meant the harmonious action of individual muscles in a complicated muscular action. It is controlled by centers in the cerebellum.

Fatigue is caused by: (1) The consumption of those substances (particularly carbohydrates) which supply the muscle with energy; (2) the accumulation of the waste products of contraction, particularly sarco-lactic acid and carbon dioxide.

6. *Respiratory function.* "Respiration is the process by which oxygen is absorbed into the blood and carbon dioxide exhaled. The assimilation of the oxygen and the evolution of carbon dioxide takes place in the tissues as a part of the general nutritive process, the blood and respiratory apparatus constituting the media by means of which the interchange of gases is accomplished."

Residual air is the air which remains in the lungs after every effort has been made to empty them; it is equal to about 100 cubic inches.

Vital capacity is the amount of air which can be expelled from the lungs after the deepest possible inspiration; it is the sum of the complemental, tidal, and supplemental air, and is about 225 to 250 cubic inches.

7. BLOOD. *Composition:* Plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.). There are also *platelets*, which are very small, colorless, irregular shaped bodies, about one-fourth the size of the red corpuscle.

Specific gravity: 1055 to 1062. *Reaction:* Alkaline. *Amount in body:* About one-thirteenth of the body weight. *Time required for a complete circulation:* About 23 seconds.

MATERIA MEDICA AND THERAPEUTICS.

1. A *solvent* is a liquid which holds another substance in solution. *Three principal solvents:* Water, alcohol, and glycerine.

2. *Diaphoresis* is the process of perspiring. *Three diaphoretics:* Spirit of nitrous ether, dose 30 minims; Dover's powder, dose 7 grains; alcohol, dose of whiskey, 2 ounces, diluted.

3. *Two cardiac stimulants:* Aromatic spirit of ammonia, dose 30 minims; nitroglycerine, dose 1 minim.

4. *Iodine* is most frequently administered internally as the iodide of potassium or sodium. Starch is the antidote to free iodine.

5. *The indiscriminate use of acetanilide* may cause: Collapse, chills, cyanosis, fatty degeneration of heart, liver, and kidneys, and destroys the hemoglobin-carrying efficiency of the red blood corpuscles.

6. *The dosage of medicines* is influenced by: Age, sex, weight, nationality or race, disease, pain, idiosyncrasy, body temperature, drug habits, method of administration, and the cumulative action of the drug.

7. *Cumulative action* is the property which some drugs have of producing more or less sudden and violent action, after single and successive doses have been taken with no untoward effect. *Example:* Digitalis; this produces fast

and irregular pulse, gastroenteritis, small pulse, low blood pressure.

8. *Three antiseptics useful for internal medication:* Urotropin, salol, and thymol.

Urotropin is a white, crystalline powder, soluble in water, prepared by the action of ammonia on formic aldehyde. It is used as a genitourinary antiseptic.

Salol is the salicylic ether of phenol; it is a white, crystalline powder, nearly insoluble in water, but is very soluble in ether. It is used as an intestinal antiseptic, owing to its power of splitting up (in an alkaline medium) into salicylic acid and phenol.

Thymol is a phenol contained in oil of thyme; it occurs in large crystals, of aromatic odor; it is soluble in fats and oils; and liquefies when treated with chloral or camphor.

9. *Three indications for use of opium:* To relieve pain, to produce sleep, and to check excessive secretion.

10. *Hypodermoclysis* "is a method of applying remedial agents through the skin. As a rule, 0.6 per cent. normal salt solution is used—a dram of table salt to a pint of boiled and filtered water. The site preferred is the anterior wall of the abdomen or the ilio-lumbar region, above the ilium and below the ribs. Thorough asepsis is necessary in the technique. An ordinary fountain syringe with a moderate sized needle is all that is required. The solution is best used at a temperature of from 110° to 115° F., and from four to eight ounces are employed. The method is extremely useful in conditions of shock, hemorrhage, diarrhea, uremia and in toxic states generally." (Butler's *Materia Medica*, etc.)

CHEMISTRY.

1. Yeast fermentation of sugar produces alcohol (C_2H_5OH) and carbon dioxide (CO_2).

Cane sugar, under the influence of yeast, is slowly converted into dextrose and levulose, which are then fermented to alcohol and carbon dioxide.

Milk sugar is first inverted by yeast, and then alcohol is formed; this occurs slowly.

Grape sugar, under the influence of yeast, is converted into alcohol and carbon dioxide.

2. The *fixed oils* are glycerides, and are capable of saponification. The *volatile oils* are mostly hydrocarbons, and are not subject to the same decompositions as the glycerides.

Three fixed oils used in medicine: Castor oil, glycerine and oleic acid.

Three volatile oils used in medicine: Oil of peppermint, oil of anise, oil of cinnamon, and oil of gaultheria.

3. *Ammonia gas.* The molecule consists of three atoms of hydrogen chemically united to one atom of nitrogen, NH_3. It is a colorless gas, with a pungent and irritating odor and a caustic taste; it is very soluble in water, also in alcohol; it does not burn readily. It combines with water to form an alkaline liquid containing ammonium hydroxide. It combines directly with acids, without separation of hydrogen, to form ammonium salts:

$$NH_3 + HCl = NH_4Cl.$$

4. Cow's milk consists of:

Water	87.00
Solids	13.00
Fat	3.66
Milk sugar	4.92
Casein	3.01
Albumin	0.75
Proteins	3.76
Ash	0.70

5. UREA. *Chemical formula:* $CO(NH_2)_2$. About 500 grains of urea are excreted daily by an average adult.

PHYSICAL DIAGNOSIS.

1. *Physical signs of aneurysm of the thoracic aorta:* Sometimes a bulging in the precordial region, visible pulsation, with a thrill on palpation, localized dulness on percussion, and a "bruit" on auscultation. One radial pulse may show diminished volume and irregular rhythm. There may be tracheal tugging.

2. *Cardinal symptoms in diagnosis of appendicitis:* Pain, beginning near the umbilicus, and settling in right iliac fossa, near McBurney's point; rigidity of right rectus muscle; tenderness on pressure over McBurney's point; nausea or vomiting; obstruction to passage of feces or gas.

3. TOPOGRAPHY OF HEART AND ITS VALVES. A line from the lower border of the second left costal cartilage (one inch from sternum) to upper border of third right costal cartilage represents the *base line;* the *right side* will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth intercostal space, three and one-half inches from mid-line); the *left side*, from left end of upper border to left of apex. The valves are: Aortic, mitral, tricuspid, pulmonary (and Eustachian and coronary).

The *aortic valves* are behind the third intercostal space, close to the left side of the sternum. *Pulmonary valves*, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. *Tricuspid valves*, behind the middle of the sternum, about the level of the fourth costal cartilage. *Mitral valves* behind the third intercostal space, about one inch to the left of the sternum.

4. Normal temperature of the body is 98.6° F. Normal pulse rate is about 16 to 18 per minute.

5. Arteriosclerosis.

PATHOLOGY AND BACTERIOLOGY.

1. *Intoxication and infection.* "In one class of diseases the infecting microbe remains localized at the point of inoculation, and is never or only exceptionally found in the fluids of the body, the general symptoms of the disease being due to absorption of the toxic products. Such are true *Intoxications*. In other cases the microbe is found circulating in the blood throughout the body and finds lodgment in most of the organs. These are called *Infections*. Tetanus is the type of the first class; anthrax, of the second." (Stengel's *Pathology*.)

2. *Phagocytosis* is the property of certain cells (such as some of the white corpuscles) to ingest and destroy bacteria. Metchnikoff believes that *immunity* is due to the chemotaxis which exists between the phagocytic cells and microorganisms.

3. "*Thrombosis of the portal vein* is most frequently the result of infective inflammation of the vein (pylephlebitis), resulting from ulcerative enteritis, appendicitis, or similar processes involving the parts from which the portal blood is received."—(Stengel's *Pathology*.)

4. *Chronic gastritis* is most frequently the result of improper food (including alcoholic drinks).

5. *Pathologicol conditions of the lymphatic glands:* Inflammation, tuberculosis, syphilis, tumors, Hodgkin's disease, leukemia, lymphosarcoma, status lymphaticus, atrophy, hypertrophy, and degenerations.

6. *To demonstrate the amœba coli in a case of amebic dysentery:* "A satisfactory recognition of the parasite, particularly in the hands of the novice, demands that he should see it send out pseudopodia; he should observe active movement. In order to do this, the material should be reasonably fresh. In the case of feces admixture with urine is to be avoided. A drop of the suspected material is placed upon a slide and a cover-glass applied. The slide may be gently warmed, or the microscope may be kept in a reasonably warm place, under which conditions movement will be more active. Fresh specimens may be best stained by mixing with the suspected material, placed upon a slide, a drop of a watery solution of toluidin blue. This reagent acts as a fixative and at the same time stains the amebas intensely and rapidly."—(Coplin's *Pathology*.)

7. *To demonstrate the efficiency of a germicide:* "Koch's original method of determining this was to dry the microorganisms upon sterile threads of linen or silk, and then soak them for varying lengths of time in the germicidal solution. After the bath in the reagent the threads were washed in clean, sterile water, transferred to fresh culture media, and their growth or failure to grow observed. This method also determines the *time* in which a certain solution will kill microorganisms, so is advantageous." (Macfarland's *Bacteriology*.)

8. *The Widal reaction:* "Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes." (From Thayer's *Pathology*.)

9. *Bacteria most frequently causing puerperal infection are:* Streptococcus pyogenes, staphylococcus pyogenes aureus, gonococcus, bacillus coli communis, bacillus diphtheriæ, bacillus ærogenes capsulatus, bacillus typhosus.

ETIOLOGY AND HYGIENE.

1. Malaria is *caused* by the plasmodium malariæ, but *carried* by the anopheles mosquito. The cause of yellow fever is not yet determined, but it is *carried* by the stegomyia mosquito.

Prophylaxis of malarial fever. Individuals should use mosquito netting around their beds and wire gauze in doors and windows so as to keep out the mosquitos as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also efficacious.

To prevent yellow fever in the tropics: All cases of the disease should be isolated; houses should be protected by mosquito netting; mosquitos should be killed; swamps should be drained.

2. Impurities in water may be classified as: (1) Mineral, (2) vegetable, and (3) animal. The presence of organic matter is deleterious, because it may indicate fecal matter, with pathogenic bacteria. The processes employed for the detection of the various impurities are too lengthy for description here, and also too technical and complicated for use by the practising physician.

3. *How* antitoxin produces immunity and effects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantities will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitasato), or to a particular influence exerted by the antibodies upon the living cells of the organism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucocytic and chemical forces. Ehrlich's side-chain theory assumes that every toxin contains toxophore molecules having direct toxic action, and haptophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attacked organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly arrived toxin, using up their combining power before they can reach the tissue cells." (Potter's *Materia Medica*, etc.)

4. Infantile paralysis is believed to be infectious, but the specific microorganism is not yet demonstrated. Quarantine, as for any other infectious disease, affords the best way of protecting the community.

5. *Hepatic abscess* is *caused* by: Microbes, ameba coli, parasites, biliary calculi, cholangitis, traumatism, and embolism, septic processes of circulatory or digestive tract. *Cardiac hypertrophy* is *caused* by: Arteriosclerosis, nephritis, prolonged muscular exertion, exophthalmic goiter, aortic disease, mitral regurgitation. *Edema of the lungs* is *caused* by: Infections, nephritis, arteriosclerosis, some cardiac lesions, pregnancy, and alcoholic excesses.

PRACTICE.

1.

	MEASLES.	SMALLPOX.
Incubation	10 days.	12 days.
Prodromes	3 days. Coryza, cough, etc. Koplik's spots.	3 days. Rigor, high fever, headache, lumbar pains.
Character of eruption.	Bluish papules; swelling of face; discrete or confluent circular outlines.	Macules, papules, vesicles, and pustules; discrete or confluent.
Parts first affected	Forehead, face, or neck.	Forehead.
Desquamation	Furfuraceous	Large crusts.
Duration	7 to 10 days.....	3 weeks.
Complications and sequels.	Eye and lungs; tuberculosis.	Larynx and lungs.

2.

MYALGIA.	NEURALGIA.
Skin is normal.	Skin may be inflamed.
Pain is increased by muscular contractions.	Pain is increased by pressure.
No skin eruptions.	Frequently skin eruptions are present.

3. *Principal forms of insanity:* Mania, melancholia, paranoia, idiocy, imbecility, paresis, dementia, delirium. *Most common causes:* Heredity, civilization, alcohol, syphilis, narcotic drugs, severe mental strains, depressing emotions, shock, trauma, autotoxemia, organic brain diseases.

4.

	CROUPOUS PNEUMONIA.	CATARRHAL PNEUMONIA.	PLEURISY.
1. Mode of invasion.	One or more severe rigors. Often vomiting.	Generally after bronchitis, or collapse, and without distinct rigors.	Frequently none, but sometimes several, not severe rigors.
2. Sensations about the chest.	Pain in the side at first, not stitch-like, but more dull and diffused.	Pains about the chest, but not specially localized.	Severe, stitch-like pain in side, increased on respiratory movements.
3. Cough.	Hacking, or in paroxysms.	Short, hacking, and painful.	Slight, and patient tries to repress it.
4. Expectoration.	Considerable; viscid, tenacious, "rusty."	Often less than before; not "rusty."	Absent, or very slight, and of no special characters.
5. Disturbance of breathing.	Very rapid breathing, and much perversion of pulse-respiration ratio, but not proportionate feeling of dyspnea until the later stages, when dyspnea is marked.	Rapidity of breathing increases when it occurs in bronchitis; dyspnea may be marked.	Quick, shallow breathing at first, but less disturbance of pulse-respiration ratio than in pneumonia. Later on, more or less actual dyspnea according to amount of pressure.
6. Degree of pyrexia.	Considerable; temperature usually high, 103°, 104°, 105° or more, and runs a regular course. Skin peculiarly hot and dry.	Temperature high, but there are considerable remissions, at irregular intervals.	No regularity in course of temperature. Skin not acridly hot.
7. Aspect of patient and general condition.	Marked flushing of face, often unilateral. Malar cyanosis. Herpes round mouth.	Face is flushed. Often much anxiety and restlessness, with loss of flesh and strength.	Nothing special. No particular prostration, or tendency to cyanosis unless dyspnea becomes marked.
8. Physical signs.	At first, fine crepitations, followed by signs of consolidation, viz., diminished movement, increased vocal fremitus, dulness, bronchial or tubular breathing, increased vocal resonance, etc. Usually one base is affected. The side is not notably enlarged, nor is there displacement of organs.	There may be signs of consolidation in scattered spots, with râles. Both lungs are usually involved in irregularly scattered patches.	At first friction-sound or fremitus, succeeded by signs of fluid, viz., side often enlarged, movements interfered with, diminished vocal fremitus, dulness occasionally movable, weak or suppressed breathing. Usually on one side, and often displacement of organs.
9. Course and termination.	(1) Often a marked crisis from 5th to 8th day: (2) death; (3) gangrene of lung; (4) abscess of lung.	No crisis, and course often prolonged or followed by acute phthisis.	No crisis, and course very variable.

(Wheeler and Jack's *Practice of Medicine.*)

BIRTH RATES, OVERPOPULATION, AND THE COST OF LIVING.

By CHARLES E. WOODRUFF, M.D.,

LIEUT.-COLONEL, MEDICAL CORPS, U. S. ARMY.

In looking over an article on birth rates and overpopulation published in the *Popular Science Monthly*, January, 1911, by Mr. Scott Nearing of the University of Pennsylvania, and to which the Medical Record referred in an editorial of May 27, 1911, it was amazing to find that some of his statistics were the same as in the book "Expansion of Races." It looks as though he had taken these facts without crediting the source, and yet in his review of this work published in the Annals of the American Academy of Political and Social Sciences he discredited both the book and its facts. Mr. Nearing, in his review, made many statements which were the exact opposite of the facts, and this is, perhaps, the reason why, in his last article, he shows that he has not the faintest conception of the significance of the data which Malthus collected and which Darwin put to such remarkable use as to make a real science of biology. Malthus proved that there was a tendency for population to increase in a geometrical ratio and crowd the food supply. He feared that a time would come when, in spite of the checks he mentioned, we would suffer dreadful distress from future overcrowding unless we took measures to keep down population so as to leave fewer to be killed by famines or in the wars due to the search for food or the means to purchase it. His fears were groundless, as the future overpopulation he dreaded was really present then, but it required a Darwin to show that the very basis of evolution of better beings of all kinds is this very overpopulation which forces a struggle for existence during which the best fitted to survive outlast the least fitted and thus cause a change of type. Those scientists who had specialized on plants and lower animals, after resisting the new generalization for twenty years, reluctantly embraced it, but those who had specialized on man and his activities—the anthropologists, sociologists, and economists—held off longer. Some of them even yet cannot bring themselves to see that nearly every social phenomenon is based on competition, as there are always more workmen than jobs and more people than available food. Part of this reluctance is due to the fact that political economy as a science was born too soon. Many of its laws were known two centuries ago, though they were first collected into a real science by Adam Smith in the last half of the 18th century, but it is now found that he made many blunders he would have avoided had he foreseen the work of Malthus. Similarly John Stuart Mill, who brought the science down to his time, correcting some of Smith's blunders, was himself woefully in error because deprived of the illumination of Darwin's later work, and was unable to use it when it did appear. Since Mills' epoch-making book there has been no economist of sufficient genius to correct the science to date and make it accord with modern biology. Thus it happens that in these few subjects it is basically wrong and will be until it applies to man the laws known to govern all other animals. Sociologists—and that term includes all who study any group phenomenon of man—are hopelessly divided and make contradictory proposals for human betterment. Some, while insisting on competition as an essential of society, are constantly making impossible suggestions to end the most basic of all competitions. It is taken for granted that man is not an animal and that there need be no destruction of the unfit; indeed, they say that there never has been overpopulation and that the unfit for survival do survive.

This is Scott Nearing's mistake. In his article he tries to show that the reduction of the birth rate is one of the reasons why Malthus' prediction of great distress has never been fulfilled, whereas the percentage of overpopulation is but little, if at all, less than a century ago. People, counted by millions, were starving to death in Russia and China this very year because they persisted in multiplying to the limit of the food production of years of good harvests, knowing full well that in the periodically returning lean years there will not be enough. In China there have been seventy famines, with millions of deaths each time, in the last seven centuries, not counting the lesser famines at all. Hindus breed like rabbits until the next cycle of poor rainfall, and then die out. In higher civilizations some of the people breed with like thoughtlessness though to less extent, so the problem of unemployment is driving socialistic legislators to distraction. It is high time that economists recognize biology. Professor Ellwood of the University of Missouri thinks it "horrible" to apply it in the strictest way, and yet in his own work on sociology, written to emphasize the biological side, there are amazing biological misstatements. On the other hand, one world-renowned economist writes me that he is in full accord with the main contention of the existence and necessity for overpopulation as a basis for competition, and another one writes me that I need not stay awake o' nights worrying over anything Ellwood says. And thus it goes.

The medical profession is vitally interested in this modern discussion of birth rates. We must recognize that the reduction of the size of families is a world-wide movement that has been going on many millenniums, but only noticed for a century. It is only one of the ways in which thinking people try to ease up the struggle for existence and make

survival more certain for their healthier, fewer, better raised offspring. But it must be known that at the present rate there are still produced enough men to overstock the labor market and make it impossible to employ them all. Mr. Nearing's article implies that overpopulation never has occurred and never will, whereas it is the basis of all advancement.

It may be remarked that few people realize what a narrow margin separates us all from starvation. Before harvest time, the last year's crop is nearly all eaten up; indeed, most foods are perishable. If all harvests were suddenly destroyed the world over, the foods in stock would not keep us alive long enough to plant the next year's crop, even if we had the seed. When a poor season brings starvation locally, say to forty million Chinese, the world cannot spare enough food to keep them alive a whole year, though we have enough money to buy it if it were available. Death is unavoidable to at least half, for they cannot eat gold. Famines, then, are permanent unavoidable phenomena, existing even where there is abundance of wealth, as in India.

Local famines, though, by leaving more food for the survivors, will never permit the world to reach that degree of distress which so worried Malthus. For many centuries the more provident Chinese and their statesmen have rather welcomed famines, because experience shows that after one is over the survivors have so much more food per capita, that there is a period of widespread comfort and prosperity, until the people by a shortsighted prolificness have restored the awful overcrowding. There is even an indisposition to fight plagues on this ground of benefit to survivors; that is, density of population is regulated automatically.

The main interest of physicians centers in the proof that a certain percentage of every society—the least efficient—are in such chronic want that proper nutriment is beyond their reach. It won't do to say it ought to be given them when we see shiploads of food leave our harbors to be purchased by abler men abroad. We cannot prevent the owners from selling to the highest bidders while there are thousands who are underfed here. And even in northwestern Europe where our food flows they have the same phenomenon of a certain percentage unable to buy that imported wheat and meat. So we witness children growing up into degenerates the world over through sheer underfeeding. Nor will it do to say that in time we will raise enough food for all, as man has been at that very thing ever since he planted the first grain. That is, there is always a demand for more food than exists, and man is always trying to raise more to prevent the distress and cause more to survive, but the only result has been more survivors with the same percentage on the poverty line, and many beyond, to die at the first poor harvest. Japan has actually terraced her mountains to supply foods when there were but ten million to feed, and she now has fifty million, among whom the struggle for food is enough to make one's heart bleed. When we have irrigated every inch where water can be conducted, and have drained every inch of our swamps, we may have some hundred million or so more mouths to feed, but the same percentage will be only partly filled or not filled at all. A thousand years will not change a phenomenon which has been going on for many millions, and which is the cause of all advances by survival of the fittest for survival.

Nor will it do the least good in this line to divide up the wealth now so unequally distributed. It may be necessary on other grounds to spoliate individuals of too much wealth, but that depends entirely upon the way they use it or misuse it. The general impression is now crystallized that the wealthy, in return for protection of their riches, must devote their lives to the people who allow them to have wealth, as the landed proprietors do in Europe, particularly in England, which is really administered by the unsalaried. Or the wealth itself must be devoted to public ends. But it will not diminish poverty to seize that wealth of millionaires to divide it up pro rata. Each man's share would feed him less than four months. If all this hoarded private wealth were invested for us the income would feed us only a couple of weeks or so. If devoted to the poor 10 per cent. of our population it would feed them ten times longer, to be sure, and permit them to raise more inefficients so that in the next generation the distress would be the same. So we had better let things go as they are, improving without revolutionizing, and doing it slowly, as we always have done, remembering that by present methods there are many more million happy, well-fed people in the world than Malthus thought possible.

The increased cost of living could also be very accurately explained by economists if they would only recognize the significance of Darwin's work. The present theories are so contradictory as to be absurd, yet each has a part truth. It is foolish to complicate the matter by discussing the value of the coins by which we are paid. The real test is whether a laborer can get as much of the necessaries of existence for his labor as he formerly did—not the amount of copper, silver, or gold he gets as compared with what he got one or ten decades ago. In Biblical times he got a penny a day, but copper was so rare that the penny supported his family fairly well, at least in a survivable way. Of what earthly use is it to a laborer to get 200 similar coppers today if they will not buy enough to support a family? He is working for the requisites of survival and does not care whether he is paid with a piece of paper, if he can exchange it for enough meat and potatoes, with something to spare for clothes and other things.

It is now acknowledged that ever since the first protolithic primitive man, or man-ape, picked up his first club or stone as a tool to help in getting food or shelter to survive, he has been constantly improving those tools to get more of that food and shelter so as to survive where otherwise impossible. Publicists still use the absurd expression, "labor-saving machines," whereas they all know that the only result in our labor competition due to overpopulation is increase of product. The sweatshop worker bending over an electrically driven sewing machine works just as hard and just as long as the needlewomen of a century ago, and gets just about as much of the necessaries of survival in exchange for an hour's work.

But there is now a vast difference in what is needed for survival. And here is where physicians can again enlighten economists in their discussions of the cost of living. Every invention permits a laborer to accomplish more than formerly, and he can demand more in exchange so he saves up or buys luxuries without which man has before survived. But in either case he is able to raise frail children who formerly perished for the want of extra foods or luxuries. There has been a progres-

sive racial physical enfeeblement from this kind of survival of the fittest for survival—the more efficient workers—and as a result we cannot possibly live as our ancestors of a few centuries back. "The luxuries of one generation become the necessities of the next." We must now have better food, clothing, and houses or we die. Moreover, when sanitation is bad, only the immune survive, and such races as the Chinese by this process can tolerate conditions fatal to us. When sick we need more attention and more materials. We also need shorter periods of labor, longer rest, and more recreation, for we would break under the old strains. That is why the laborer of the upper races makes more things by an hour's labor than ever before and gets more in exchange for them, and why human conditions have thus progressively improved since the first tool was made.

Nevertheless the same old competition from unemployment comes in, and we find idle men in the "market places" underbidding each other for jobs by which they can get enough to survive—a condition as old as the habitable earth. The only point to consider is whether a man gets enough for his work to survive, and that evidently regulates itself automatically, for if he fails to get enough he dies, though it may have been enough for hardier ancestors. The price of food also thus regulates itself automatically, and no human laws have ever succeeded in getting it down to the purchasing power of everyone, though innumerable attempts have been made. The birth rate keeps it automatically, just out of reach of the purchasing power of the submerged tenth, no matter what the actual price or how greatly the crops are increased by modern methods.

Writers are constantly befogging this matter by lugging in the question of the wages for special ability. We must deal with the average man, no matter what his trade, though certain employments are necessarily confined to the more intellectual who are the exceptions. Labor is worth only the increased value it gives to materials worked on, and that depends solely on the demand for the product. Among a hundred thousand stone cutters there may be but one who can make a beautiful carving, but he will not get a cent for his work unless there is a demand for it. He may die of starvation, and even if his work is demanded it may not bring in much, for the supply is great when he can duplicate it. An artist often gets less than mechanics, but after he is dead and the supply of his work limited forever, the demand throws the value up enormously. In like manner, any man who by exceptional ability can produce works of value is paid in proportion to their value. All these matters affect such a small percentage of the human race that we can ignore them in dealing with the wages of mechanics. The rule is absolute—the normal wage the world over, by reason of the competition of overpopulation, is and always has been the bare necessities of existence for man and wife and a baby. Those below the average cannot get these necessaries of their own exertions. No ordinary mechanic can support many children, and never could. These are cruel facts, and by ignoring them sociologists are doing much injury in their efforts to improve conditions.

Adam Smith first pointed out the natural cost of living (our total energy), but in measuring the price of food he made a remarkable blunder, due to his ignorance of overpopulation. He tried to measure the value of wheat by the labor of production, whereas its value is what the competing too numerous consumers are willing to pay for it to keep alive; and that amount is practically the whole labor of the lowest self-supporting layer of society. The labor of production doesn't enter into the problem except secondarily, for no consumer will give more labor for it than he would expend in producing it himself, omitting the costs of transportation and exchange. Modern machinery has enormously reduced the labor of production, but the actual price has not varied in like proportion, because the demand of increased population keeps exact pace with larger crops, and the price of our daily bread is the same as ever—our daily labor—omitting the other necessaries for the sake of brevity. The farmer grows much more food for his time than ever before, and would get rich if he could demand an equally increased amount of goods in exchange for his surplus. But he is as poor as ever, for several reasons. His own needs are more, and if his labor was very valuable there are competitors who would overbid him for his rented farm. This actually occurs, and the rents rise so that he has left only enough to live on. This is why the tendency is for farms to diminish in size to the point just sufficient to feed a small family and give a tiny surplus to sell for other necessaries. The land owner is the real beneficiary of the competition of overpopulation. He gets the unearned increment, and lives in town. That fact is so galling that many economists think it will be taken away from him in time.*

The results of all these checks and counterchecks is that the measure of the cost of food is what we can pay for it, and that the labor of the producer tends to equal that of the consumer. The two fluctuate slightly, but are practically equal from age to age. Increased crops, then (or lessened cost of production), merely increase the percentage of urban population. The submerged tenth are submerged because they have not enough bodily or nervous energy to equal that expended by a farmer, and, of course, they cannot get the food he grows. In times of scarcity food is high, no matter how little labor its production cost, and the poor, in order to survive, would sell their children, their wives, and even themselves, and at the present moment this kind of voluntary slavery exists in the majority of the human race, though it is disguised in form. To their minds it is better than death by starvation. When America cannot take this surplus population from Europe, what is to become of them in times of scarcity? and what will our state be?

The special temporary conditions in new coun-

*Rev. Monroe Royce in his book "The Passing of the American" mentions the enormous rentals paid by French farmers for the most desirable lands, $500 to $1,000 an acre. A "farm" of two or three acres is barely enough to support a family of six, all working who can to raise the six or seven crops a year and producing as much as forty-two times the yield per acre of many an American farm. If a man is rich enough to own one of these three-acre farms—$60,000—he lives in town supported by the rent. It seems that all working men (farmers and all) are drifting to a state of affairs in which they support themselves by working with the tools belonging to some one else, and land is here classed as a tool. If the farmer doesn't pay his rent some one equally efficient will, and a more efficient man will give more. Any one of the 5,000 shelterless vagabonds of Berlin would willingly pay more rent for the sake of the roof and food, but they are too feeble, mentally and physically, to do the work. The race is to the strong—and that's why so many weakling immigrants stop in New York while there is Western land almost for the asking.

tries like the United States, Australia, and New Zealand have also befogged some writers. There was vast wealth and food untouched by savages too stupid to get them. The newcomers became wealthy. Even the few laborers, by reason of high wages due to the great demand for them and the small supply, became proprietors and employers who had to send abroad for employees and tenants. Our immigration streams are thus composed of those who cannot make a survivable existence abroad—to use a rather tautological term—the failures in an overpopulation. Consequently, they are underbidding for jobs, and in time their wages will be the same as in Europe—mere existence, meat once a week, black bread, and six sleepers to a room. Indeed some of them are in that state now.

The cost of living counted in gold dollars is constantly rising the world over because gold is constantly diminishing in value with the increase in its amount. The actual yearly production of gold does not matter much now, because it is such a small percentage of that already hoarded. The process is the same as when the Mexican silver mines flooded Europe and that metal became so cheap that much more of it was needed for a day's food. Prices of labor and foods rose enormously, but no one got any less or more food for his efforts. In America, the glut of gold makes wages increase too, but not in proportion to materials, because of the greater relative increase of laborers. As shown by John Stuart Mill, the laborers in Europe are temporarily benefited by the emigration drain until the birth rate restores overpopulation and they do not so keenly feel the loss of value of gold and silver; but in America the laborer is damaged by every newcomer and is getting frantic, for he cannot see the reason why a day's labor does not bring the surplus and luxuries it did a generation ago. In time as immigration fills up the land and increases this competition, we will find that wages will sink to what they are everywhere else, just enough to survive in times of plenty, but with distress or even starvation after years of poor harvest. Saving will be possible only to those of exceptional ability, and not to everyone as it was when we had wealth to get for the taking, and the demand for workers could not be filled. These are the brutal normal conditions in the rest of the world as pointed out by economists long ago, and are being slowly brought about by unrestricted immigration. We must expect the cost of living to increase in America as measured by what we can buy with a day's work or day's wages, no matter whether the workmen are paid with a few grains of dear gold or few ounces of cheap. In passing it may be remarked that by a curious delusion, the laborers who are so injured by every newcomer very strongly object to restriction of immigration, while those who are advocating restriction or even exclusion are the well-to-do of the employer class who need cheap labor and are benefited by immigration.

The medical profession must face the growing conditions which, as in Europe and Asia, make it impossible for a sick workman to hire help—doctor or nurse—to buy medicines, or even the food to tide him over until he can again earn a bare existence. Moreover, it takes a wise man to foretell whether the fewer exceptional men who can save for a rainy day will be able to support these indigent sick, all the Lloyd-Georges to the contrary notwithstanding. As for taxing everyone for the purpose, that only increases the cost of living and will prevent a few more from getting the bare necessities. We've been living in a fool's paradise, paved with gold, whose brilliancy has so blinded us that we cannot see into what we are drifting by our over-generous call to the failures of the world to come over and share our beef, and wheat, and coal and iron. We would like to get the wealth back now.

These facts are beginning to dawn on German thinkers, who have likewise been blinded by unexampled prosperity and are now burdened by an army of unemployed, who actually slaughter horses and dogs for food to sustain life. As for New Zealanders and Australians, protected in their wealth by the enormously expensive navy of Great Britain, they too are thinking of the future. We cannot do as they do, for we must protect ourselves. They would not last a year if it were not for their protector keeping out Asiatic and European invaders. The cost of living includes the cost of preventing death in all forms, and there are starving millions in Asia ready to steal this wealth of food in Australasia, but are deterred by the British navy. Australians, therefore, can try all kinds of social experiments out of our reach. Late reports show that they are living beyond their means through supporting the inefficients.

It is evident then that the actual amount of gold given for a day's common labor depends solely on the local cost of living, and it cannot be less. In Japan the wage is between 15 and 20 cents, for that is ample where the houses are cheap, little clothing, fuel, and furniture needed, and the coolie intelligence so low as to need few relaxations. Mechanics and artists can get 50 to 70 cents and this partly relieves the wife of the necessity of laboring. In India it is far less, but it purchases what the two dollars do in New York—survival and but little more. That is, the natural wage the world over is just enough to keep a small family alive. If a man gets more, he is more or less exceptional. If less, he is a pauper. The time is long past when an American laborer can live in comfort and save. He is already near the poverty line. The time is near when no unexceptional man can weather a lean year—the conditions of Russia now. When will economists wake up to biological facts?

Industries could not exist if there was not an idle mass to call on to fill vacancies instantly, for if a single department cannot get men, the whole works must close. If every locomotive engineer were occupied and a sudden disaster overome some of them and interfered with the milk trains of New York City it would kill 50,000 infants in a week. To avert that disaster other trains would be abandoned and interfere with or stop other business, obligations would not be met, and panic would result. That is, civilization depends upon an unemployed mass for emergencies, and if there was enough food to go round there would be no competition compelling the unemployed to jump into the vacancies. If any of the bizarre plans to end unemployment could possibly succeed, it would thus destroy civilization. It is sad to think that poverty is necessary, but sadness should not lead us to deny the inevitable. What will result when we evolve into some form not human—superman—no one can tell, and it is too far off to bother about. If the unemployed are put on public works, as now seems to be the fashionable theory, taxes are increased and all self-supporting men at the poverty line are pushed over into want, for on the last analysis all taxes come

from the workers no matter how we disguise them.

No man has ever been able to predict events accurately more than fifty years, and then only as a lucky hit when new factors did not enter to disturb calculations. Estimates of future population are notoriously erroneous. So we do not know what will be our state a century hence, nor whether we have intelligence enough to create artificial conditions raising us above the normal elsewhere. Of only one thing can we be certain, and that is, the more numerous we are, the less wealth will there be for each of us, and the cheaper will be labor. What percentage will work for mere existence as in Europe, is beyond our ken, but it will be more than now. This alone will have a vital bearing on the medical profession, and the present reduction of the number of medical students per 100,000 of population must continue, or few can make a living at it.

As illustrations of the above truths, a twenty dollar suit of clothing is almost of the same quality as a twenty dollar suit forty years ago, but the price is really half as the purchasing value of the present dollars is only half of what it once was. From farm to tailor the coat is made in half the time. Now, as the workman gets more of these dollars for a day's labor, he really gets more clothing in a year than he ever did before in the higher civilizations. Everything else he uses is produced more cheaply, too, from the use of better tools. A short, slow ride in a street car formerly cost us five cents, but by better machinery we now get a quick, long ride for a much cheaper five-cent piece. That is, transportation costs only a fourth or fifth of what it did a generation ago. Everything is cheaper from the same causes except luxuries and food, and the latter is under an entirely different law, due to our old habit of breeding to the limit of its production. Man needs more of everything else to survive and gets it. He needs more comforts and rest and gets them, too, but he needs exactly the same weight of food as ever. Modern machinery and methods enable a farmer to raise more food, as previously explained, but more people keep the price up to our working limit. It is nonsense to compare the dollar a bushel wheat of recent years with the shilling a bushel of two centuries ago without comparing the purchasing value of metal and how much of it a man can get by a day's work. The rule is absolutely fixed and invariable—the cost of the laborer's wheat measured by the labor of getting it never varies in the long run, though it is subject to tremendous fluctuations in a new country like America. Nevertheless, as we must have a little better food and other kinds of food every generation, to feed the weaklings now saved but who formerly perished, we actually do get more and better food than ever before, but it takes the same amount of effort—our limit of safety.

All this is due to nature's delightfully simple plan, of letting us breed inordinately and then killing those who cannot get this food, the survivors being those who can survive by their own exertions unless the charity organization steps in to save those the Lord doesn't. Clergymen who advocate large families are fond of saying that "The Lord will provide the food," but the trouble is, that is the very thing the Lord cannot do as He confesses in the famines recently raging in Russia and China. Political economy needs a new foundation, and curiously enough that foundation is an economic law known many ages before there was a science of economics: "The Lord helps him who helps himself," the others shall not possess the earth nor the fulness thereof. This new basis, then, is that no matter what are the necessaries for survival, men are too numerous for all to get them and food goes to those who can get it. Might makes right in the matter of living, and in a lot of other things where we think it should not.

As for the cost of meat, it must be remembered that it is entirely out of the reach of the vast majority of humanity—except, of course, a little fish daily or some pork now and then. For centuries the European peasant could not afford it more than once a week. One of the reasons for the expulsion of Christians from Japan in the 17th century was the fact that they were teaching the peasants to eat the invaluable draft cattle. We have been a beef raising country and have been deceived by its local cheapness, but our increasing numbers are quickly reducing the per capita amount available. It is already out of reach of many, and as the immigration continues it will be so scarce that few mechanics can afford it more than once a week. Moreover, as our farms increase and crowd the grazing area, it will cost more to raise beef and this will put it out of reach of many more. The enormous present cost is perfectly natural, but it is bound to bring diseases of lack of nutrition and perhaps reduce our stature to that of similar ethnic types of Europe.

Finally, it is time to think of the future American descended from those elbowed out of overpopulated Europe because unable to make a living there, but who could do it here where competition did not exist. Millions of them were eliminated this way in the 19th century, and the result has been a progressive rise in the efficiency of the stay-at-homes who are now inconceivably rich, numerous and powerful by reason of their abilities. This kind of elimination has been going on for some thousands of years, so that for a long time all great ideas have originated in Northwestern Europe. The breeder of race horses would be an idiot to breed from only the mares and stallions who get beaten on the race course, and yet there are hundreds of writers who say that we are breeding up, as in Adams County, Ohio, the finest type of man in the history of the world, from those who failed in the race of life in Europe! Great Britain deported her criminals for two centuries and we got a lot of them, so we now have about three hundred times as many murders as England. The newcomers kill our Presidents. The greatest elimination of inefficients was from Ireland, which now has left a splendid, moral, industrious population of increasing prosperity and a minimum of crime, while we have had two great conspiracies of wholesale murder—the Molly Maguires and MacNamaras—and perhaps others.

Surely it is time for political economy to learn a little of survival of the fittest by elimination of the least efficient due to universal overpopulation. Then we can suppress the Ellwoods and Scott Nearings, who won't learn.

There are historical records that law makers for three thousand years or more have been trying to circumvent nature and raise the price of labor and lower that of necessaries while increasing the number of laborers. Almost every conceivable Quixotic plan has been tried,—fixing prices, forbidding or taxing imports or exports, employing the unemployed, varying the size of the coins and a long list of other idiotic performances,—but the net result is absolutely nothing. To-day, as always, the

average man everywhere is struggling for a mere living and cannot raise all his babies without the labor of his children themselves, and the same old tenth cannot keep themselves alive. There is some general law in this proportion of the submerged, for it seems to be the same everywhere—about a tenth, more or less, are ready to die when the harvest fails. It shows how pitiful have been our efforts to end the competition and elimination by which nature evolves higher types which can live by millions where savages perished from inefficiency.

Can we reduce the birth rate so that competition will end, or is there reason to believe that no matter how high we progress there will always be a submerged tenth to excite our pity? The more prosperous and higher the social layer of those who make their own living, the smaller the birth rate; the clergy and nobility are excepted, as their numerous offspring are raised by money contributed by the producers. The higher types of the proletariat, therefore, tend to die out as the birth rate is too small, and the race is kept in existence by those families who have more than enough babies for the survival of their class. The human race then can survive only because there is a general tendency to reproduce more than enough and let them compete for existence.

These are the reasons why all socialistic schemes for ending poverty and distress have failed so far and will always fail—even while the general state of the efficient is constantly improving. Malthusian plans, also, though beneficial to an individual family, cannot possibly alter the conditions of the race or any branch of it, for nothing can alter the basis of our existence. The inefficient poor will be with us always, probably a tenth, and those we must support entirely may be 3 per cent., as at present, but more exact predictions are unwarranted.

Recent studies have shown that our 3 per cent. (dependents and outcasts) are all cases of arrested mental development, while in the 3 per cent. of very exceptional men, mental development may go on to 40. The average mind ceases to grow some time between 14 and 21. If it ceases earlier the person sinks into the submerged tenth. Every year of development after 21 raises it into the well-to-do class a little further.

"Scientific management" or "efficiency," of which we hear so much at present as though it were something new, is as old as man. Its only effect when widely adopted is to increase the output of a day's labor and thus diminish the value of the goods measured by the effort to get them. It has no effect whatever on wages or the difficulty of getting food. It adds to the per capita of the world's wealth but not its food. We have now an enormous and increasing public wealth of roads, houses, water and sewage works, and means of defense, and in the future we shall have better clothes, but we will work to get them just as hard relatively as now. What use will it be to increase efficiency so that we may all wear purple and fine linen, if we continue to breed so that the food will never go round? The unskilled workingman's standard of living in America is the same as that of medieval nobles, but he is on the poverty line all the same.

All this sounds pessimistic, but its purpose is to show why past efforts to end poverty and the high cost of living have failed, and yet why general conditions are constantly improving in spite of the unavoidable evils connected with race advancement. We can lessen the evils still more, but we must recognize the necessity for child labor and make it as wholesome as it was before the industrial age brought the deadly factories. Schools must train workers as well as citizens. Men who procreate beyond their ability to feed and thus allow the babies to die, are morally in the class of murderers. They must at least be considered public enemies and deprived of citizenship, if not imprisoned. They have depended on the Lord long enough, and the public burden of baby saving is irksome. People who depend on public relief of any kind—from dispensaries to almshouses—must not be permitted to have any share in public affairs; that is, the franchise must be limited to the self-supporting. These and many other lines of effort will surely lessen evils we cannot eliminate. We do not seem able to hasten the reduction of the general birth rate as Malthus advised, and it is fortunate we cannot.

Perhaps it would be clearer to state the proposition in more general terms, by dividing the cost of living into two parts, first that of the actual food needed to keep alive (carbon, nitrogen, water, etc.), and, second, of all the rest (protection from injury of all sorts, and that means clothing, housing, police, etc.). Recreation though necessary will be ignored as it need not cost a cent, but might cost a fortune. The cost of food except in new countries never varies from century to century the world over; it is something near three-fourths of the total energy of the least efficient self-supporting person, the rest of his necessaries require the other fourth of his total energy, but he gets more of these necessaries every decade. This man cannot marry unless his wife helps to obtain food or virtually supports herself. If disease or babies come, the family drops into the submerged tenth who cannot live without aid of their betters. The average man the world over is so much more intelligent and energetic, that he can obtain food for himself and wife and three children, providing the wife helps in some way, but their other necessaries are reduced to the minimum. If there are more than three helpless children, all are in poverty, if less they are opulent. Only a small percentage of the men of any high race, about one-tenth, are able to support a wife and three children without any aid from them; that is, they are able to hire help. Those who can raise a large family without their assistance—the rich—are as few as those who are public paupers. This is in accordance with the law of averages discovered by Quetelet a century ago, the average barely survive and the exceptional men on each side—the poverty stricken and well-to-do—are in equal proportions at any one place. But the higher the civilization the more do men vary from the average—more paupers and more millionaires. Savage tribes have neither class.

In every characteristic the more exceptional a man is, the fewer are in his class. The most efficient get food by the expenditure of only a fraction of their energy, the rest goes for luxuries or for hoarding. The cost of living in every case is measured by the energy of the fittest for survival—the self-supporting—the average who make the species—and competition for food urges them to bid the price up to their limit. If we measure the cost of living by the effort to make a living, every fact in history shows that the cost of living is unchangeable. It is not increasing except in new countries. It cannot increase in the old, as periodical famines remove competitors when too numerous, and emigration gives only temporary relief.

SPORADIC AND EPIDEMIC POLIOMYELITIS.

By WILLIAM HANNA THOMSON, M.D., LL.D.,

NEW YORK.

Sporadic poliomyelitis and epidemic poliomyelitis are two distinct affections, differing both in their cause and in their nature. Sporadic poliomyelitis is plainly as accidental an affection as a broken leg. A child, when heated in play, sits on a cold door step, or lies down on cold ground, and that night wakes up with a backache, which is commonly associated with slight fever. In the morning it is found unable to move its legs. After a few days one of its disabled legs recovers completely, but not so the other, certain groups of its muscles remaining paralyzed, and then undergoing an atrophy which lasts for life. Now none of this child's young brothers or sisters, nor any of its companions catch this disability from it, because it is no more communicable than a sprained ankle or a dislocated shoulder. There is no case on record of this long, well-known form of poliomyelitis spreading from one person to another, and thus becoming epidemic.

But there is a poliomyelitis which is epidemic. That fact of itself should call for investigation to find whether this form does not show characters which wholly separate it from our old familiar sporadic form. Affections like inflammations of joints, which have certain features in common, are often confounded together, such as rheumatism and gout. But neither rheumatism nor gout differ so essentially from one another as on investigation we find to be the case between sporadic and epidemic poliomyelitis. This difference is clearly illustrated by the findings of pathological anatomy. In the sporadic form only the anterior horns with their motor fibers are changed, the affection being strictly limited to parts of the spinal cord supplied by a branch of the anterior spinal artery. In epidemic poliomyelitis, the changes instead of being limited, involve, according to Flexner, the spinal cord, intervertebral ganglia, medulla, pons, cerebellum, and meninges, with injury to the white matter of both the spinal cord and brain. Moreover it induces serious changes in the whole lymphoid tissue of the body including the agminated glands of the intestine. Besides these, there occur visceral lesions in the lungs and in the liver.

These facts readily explain another significant contrast between the two affections. Sporadic poliomyelitis but rarely causes death, or even much constitutional disturbance, all on account of its limited extent. It does not invade the posterior horns nor cause transverse myelitis, nor ascending or descending cord changes. The patients subsequently enjoy perfect health, with the exception of localized paralysis. Epidemic poliomyelitis, on the other hand, is a fatal disease, the death rate varying from six to ten per cent. in different epidemics or localities. In epidemic poliomyelitis, notwithstanding the widespread derangements which it occasions, the disease usually passes on in a remarkably short time to complete recovery in most patients. This is another striking contrast, for the disabling results of sporadic poliomyelitis are both invariable and life-long in their duration.

We would, therefore, emphasize anew the great and contrasting anatomical changes which epidemic poliomyelitis causes, so as to show that these two affections no more resemble one another than smallpox resembles urticaria. Epidemic poliomyelitis, unlike sporadic poliomyelitis, causes enlargement of the mesenteric glands, and enlargement of the spleen, thymus, and tonsils, and superficial and deep glands of the neck, and focal necroses of the liver cells, besides all those widespread changes already mentioned in the substance of the cord and brain. Hence it presents all the characters of a virulent infection, and therefore can, and does become epidemic. Also that instances of it can occur *de novo* or sporadically is no more likely than in the case of typhoid fever.

Now we have said that these two affections differ altogether in their etiology and pathology. We have already discussed the mechanism of that frequent cause of disease and of death, commonly termed "catching cold" (Medical Record, February 17, 1912, page 301). Catching cold is caused by some localized shutting off of arterial blood from the part. This occurs whenever a local chill affects a part of the surface of the body which has vasomotor associations with internal parts or organs. The vasomotor nerves ramify on the coats of the arteries so as to control their caliber, either contracting or dilating same, according to the functional needs of the part. Among other laws of vasomotor association, which we cited, is the intimate association between the vasomotor nerves of the skin and the circulation of parts underneath that cutaneous area. No cells of any texture, such as those of the mucous membranes, can suffer any withdrawal, however brief, of any arterial, but not venous blood without injury. But this is particularly the case with the nerve cells, for these at once are disorganized by the shutting off of their arterial supply. Hence if a child has a local chill on any part of the skin over the spinal cord, it is then very liable to suffer from the changes in its arterial circulation, which in this case are limited to the branches of the anterior spinal artery.

In both diseases we have children affected much oftener than older patients. This may be explained by the vulnerability in children of the spinal cord to injuries, especially as the pyramidal tracts are so late in their development, and thus more liable to derangement. In the sporadic form the growth of the leg may be so affected as to become shorter than the other, and from the first its vasomotor nerves are so involved that the limb becomes cold. As time goes on, the atrophied muscles produce not only lameness, but deformity of the joints, which have to be specially treated, so as to compensate for this disability. Such particular and localized changes do not occur in the epidemic form.

The incidence of the epidemic form is strikingly according to the season of the year, namely, during the summer months, while the sporadic form commonly occurs during cold weather. The epidemic form has occurred in Europe in scattered localities, in France, Italy, Germany, and Denmark, more especially in Sweden. In the United States it has been very prevalent, occurring in the majority of the states of the Union. There can be no question that the epidemic form is of the nature of an infection, and therefore the question of its communicability is of great importance, that is, whether it may be directly communicated so that it may be properly termed "contagious," or indirectly as in typhoid fever, by some intermediate carrier. Such a question cannot well be determined in crowded cities, hence the importance of a careful study of the epidemics in purely rural communities. Thus I

was called in consultation to see a boy living in an agricultural neighborhood in Dutchess County, New York. He was then paralyzed in both legs, and had considerable difficulty in micturition, which never occurs in the sporadic form. I learned that the boy who sat next to him on a bench in a schoolhouse had been taken with the disease eight days previously, and died from it in four days. I was then taken three miles to a house in which a young woman was comatose with all the symptoms of cerebrospinal meningitis, from which she died. I then learned that the boy whom I first saw was a cousin of hers, and that he slept in her house for two nights, five days previous to the first symptoms which she developed. So far as these cases went, therefore, they would indicate that the disease was communicated from one patient to another directly. I therefore urged the physicians who called me in consultation that they should ask for a committee of their county medical society to investigate the succession of cases in a district of about twelve square miles, where people were very likely to be acquainted with one another, impressing upon them the importance of such observations being made there, compared with any observations in large towns or cities; but though I offered to present their reports before the New York Academy of Medicine, of which I was then president, I heard nothing more on the subject.

In this connection I would refer to the great benefit which the whole medical profession received from the reports published by the Danish Government on the subject of Asiatic cholera, when it prevailed in that kingdom in the year 1853. In the year 1855 the State Board of Massachusetts published a statement to reassure the public about Asiatic cholera, which was then approaching our shores and Europe. The Board then stated that Asiatic cholera was in no sense contagious, by which they evidently meant communicable, but that it was due to a miasm diffused through the air. Both these statements were mischievous errors, because the experience in Denmark showed that no case of cholera occurred which had not been in some way connected with a previous case. Secondly, we now know that there is no miasm, and that so-called miasmatic diseases, instead of exhaling from swampy districts, are really due to animal organisms carried by the mosquito *Anopheles claviger*, and communicated by hypodermic injections by this insect. Now in Denmark the government had issued instructions to all physicians practising in rural communities, directing them to carefully note the first five patients in their neighborhood who developed Asiatic cholera, and when these reports were all collected, they afforded conclusive proof that Asiatic cholera is a disease communicated from one person to another, and that it spreads in no other way.

In the widespread epidemic of poliomyelitis in the City of New York three years ago, the symptoms of the disease were often scarcely distinguishable from those of cerebrospinal meningitis, a fact not surprising, considering how often epidemic poliomyelitis begins in the blood vessels of the meninges. Epidemic poliomyelitis, when it occurs in rural communities, is plainly a communicable disease, and hence the profession should take steps to have it thoroughly investigated by competent observers whenever an isolated epidemic is reported. In large cities, on the other hand, it is often impossible to settle how any infectious disease is propagated, whether it be measles, diphtheria, whooping cough or the rest. The one practical conclusion is that if any infection is suspected to be directly communicable, the only measure then to deal with it should be by isolation or quarantine.

70 East Fifty-fourth Street.

THE PERSISTENCE OF CERTAIN RACIAL CHARACTERISTICS.

By PEARCE KINTZING, B.Sc., M.D.,

BALTIMORE, MD.

PROFESSOR OF PRACTICE OF MEDICINE AND PHYSICAL DIAGNOSIS, MARYLAND MEDICAL COLLEGE; PHYSICIAN TO THE FRANKLIN SQUARE HOSPITAL, ETC.

Some ten years ago I made a modest contribution to anthropological literature by publishing a series of observations upon the transmission of certain racial characteristics and the modifications that these underwent when the blood of the race in question was mixed with the blood of other races. Particularly these observations called attention to the persistence of certain variations in the descendants of the American negro in the event of intermarriage with the white race, and endeavored to determine the degree of blood dilution at which they severally disappeared.

The article in question attracted unexpected attention. it was abstracted by numerous medical journals in this country, reappeared in a French publication, was abstracted by at least one in Germany, and various parts of it appeared from time to time in the lay press, sometimes with the errors and misinterpretations incident to lay journalism.

The matter has a certain medicolegal interest which has increased since the appearance of the original article, owing to various States having passed enactments against miscegenation. Since I am able to add a few recent observations to those previously made, and since the original is long out of print and the publishing company thereof disbanded, I have decided to reprint the gist of the former paper, with the additions alluded to. If further reason were necessary, I would say that in several cases wherein I have been summoned to give expert testimony upon the question here discussed, it has appeared that there have been published remarkably few, if any scientific treatises upon this particular subject, and a search of the Congressional and Surgeon-General's Libraries has been practically barren of results.

From numerous allusions found in contemporary literature, especially in the writings of continental authors, it would seem that there is a widespread and generally accepted opinion that an admixture of white blood with African or negro blood imparts certain characteristics that are extraordinarily persistent, and that however attenuated the blood mixture, the stigma may be recognized by these peculiarities. The opinion seemingly prevails that the strain may be thus verified even when wholly unsuspected and when the general physiognomic traits would not indicate its presence, thus giving to the signs a definite medicolegal value. Among the most commonly mentioned signs are certain peculiarities of the fingernails. Thus Dumas, in one of his dramas, makes the denouement turn upon the detection by this means of the imposturing of a colored woman. Eactly what the signs are is not made clear. Although I have frequently encountered the idea in literature, the proposition is usually rather vaguely defined or expressed in terms too general to

have any real ethnic value. For this reason I am at present able to refer the reader only to three writers who set forth the idea with any degree of exactness. Paul Bourget, in "Cosmopolis," says of Florent:

"Il fallait le coup d'œil d'une Yankee pour discerner sous les ongles de ce bel adolescent un peu bruni la toute petite goutte de ce sang noir déja si lointain"—It would have required the keen glance of a Yankee eye to discern under the nails of this handsome, somewhat bronzed youth, the infinitesimal drop of black blood already so distant. Here the author probably refers to that bronzing of the nail so often seen in the colored races, and which in appearance is somewhat analogous to, the discoloration produced in the fingernail of the surgeon, after prolonged immersion in a solution of mecuric chloride. The only other interpretation that I am able to give to his words is, that the flesh beneath the transparent nail showed a difference in coloration, which could be detected by the practised eye, but which would not be remarked by the casual observer.

The following extract is from Theodor Storm's Jenseit des Meeres: "Als ich auf die schlanken weissen Fingerchen blickte, erschien mir daran, anders, als ich es sonst gesehen hatte. Die kleinen Halbmonde an den Wurzeln der Nägel waren nicht wie bei uns Andern heller, sondern blaulich und dunkler als der übrige Theil derselben. Ich hatte damals noch nicht gelesen, dass dies als Kennzeichen jener oft so schonen Parias der amerikanischen Staaten gilt, in deren Adern auch nur ein Tropfen schwarzen Sklavenblutes lauft, u.s.w."—As I gazed upon the slim, white fingers, there appeared to me to be something different there from what I had ever before seen. The small halfmoons at the roots of the nails were not as with us brighter, but bluish and darker than the upper part thereof. At this time I had not yet read that this is accepted as a sure token over there, of the ofttimes beautiful American pariah, in whose veins runs even the smallest drop of black slave blood.

No less a personage than Edward B. Tyler, D.C.L., F.R.S., in his introduction to Anthropology, says: "In the southern United States, the traces of negro descent were noted with the utmost nicety. Even where the mixture was so slight that the untrained eye noticed nothing beyond a brunette complexion, the intruder who had ventured to sit down at a public dinner table was called upon to show his hands, and the African taint detected by the dark tinge at the root of the finger-nail."

Here the proposition is clearly and definitely set forth. Likewise, the idea seems to have gained considerable prevalence in the South, that the nails of the negro possess distinctive characteristics, and while one often hears the expression, "nails like a negro," yet I have failed to find any unconfused or uniform idea associated therewith. Perhaps the most prevalent notion is that the lunettes are absent, or that they are transparent instead of being like ground glass in color, and that the underlying flesh differs in color from the pale pink tinge of the Caucasian.

In view of these literary allusions and the generally prevalent belief, I formulated the following proposition:

What physical traits of the negro persist in the case of blood dilution with Caucasians, and to what degree of descent are such traits transmitted? Do the nails of negroes and persons of mixed blood possess distinctive attributes? Is it possible to verify this admixture of blood when the general racial characteristics fail to indicate it?

Two general anthropomorphic principles may be laid down; first, that in the transmission of physical characteristics of development, those that are especially marked and prevalent in the one race are most apt to be transmitted to the offspring in the event of sanguineous racial admixture, though with certain modifications, even when such transmission seemingly is contrary to the general trend of evolution. Particularly is this the case with regard to variations in the osseous system, to pigmentation, to the more or less distinctive odor of the body, the color of the iris and sclerotics, and, to a less degree, to the appendages—the hair, the teeth, the nails. Second, that a much greater range of variations is found in the male than in the female.

Another principle of transmission is that the traits of the stronger parent prevail. Now in our country, offspring resulting from the union of white men with negro women is much more common than the reverse; consequently, the characteristic traits of the negro disappear more rapidly in the offspring resulting from such unions than would be apparent in general admixtures where sex selection was equal. In the cases of union between white women and colored men that have come under my notice, the women were usually of a very inferior social order, of the Slav or Magyar races, showing marks of mental and moral degradation—very seldom were they Anglo-Saxons—and most often such unions were barren of offspring. Hence the problem practically resolves itself into observations upon dilute blooded negroes sprung originally from the union of white males with negro females.

My hospital clinic (at that time the Hospital of the Good Samaritan and the clinic of the Women's Medical College) was largely attended by both colored and mixed races. Believing that it offered a favorable field for observation upon the propositions in question, I have, with this end in view, examined in the course of the past three years over five hundred suitable cases, in order to arrive at such conclusions as might be reached from ocular observation alone.

The term "mixed races" as used herein, refers to varying admixtures of negro and white blood. The term mulatto being used to indicate the cross between the full white and the full blooded negro; the quadroon or quarter blood, meaning the descendant of a mulatto and a white person; octoroon, indicates the cross between the quadroon and the white blood, while the term sambo (Sp. *zambo*) signifies, ethnologically, the return towards the negro type, being the descendant of a negro and a mulatto.

The general physiognomic characteristics of the negro are well known and need not here be described, but it may be advantageous to refer to a few of the less known variations, some of which are peculiarly persistent, and upon which racial recognition mainly depends. Such are the changes in the alar cartilages of the nose, the pigmentary deposits about the genitalia and in other localities, the relative length of the femur to the tibia, the stretch, the shape of the hairs, and, most eminently, the variations in the nails; hence it is to these details that I shall particularly direct attention.

It is to be noted that the negro characteristics in the offspring become more evident in practically all cases with advancing years; young children showing indifferent traits, while those of the same

family, beyond the age of puberty often display noticeable negro inclinations. Especially is this true of skin pigmentation. Not infrequently have I been asked whether negro babies are not born white. Needless to say this idea is wholly erroneous. Although the offspring of even the darkest skinned parents are invariably much lighter at birth than the parents, they soon darken. Sections of the skin that I have made from still births show the pigment layer to be present. Normal negro infants are included within a color scale between light putty and café-au-lait. These and other observations show conclusively that certain markings present at birth develop with growth, and that others are not apparent until a definite age of development is reached.

To illustrate: In a recent case of miscegenation in which I testified,*a boy of eighteen showed no positive racial signs upon which conclusive evidence could be based, yet an examination of the mother, a quadroon, gave unmistakable evidence of negro blood, and an older sister gave similar, though less conclusive, evidence. I was told that the brother and sister were each octoroons, but by different fathers.

To cite another example: A boy of 6 came to the dispensary, and while I pride myself on being able to classify accurately the two races, the boy was entered as white. Later, when he returned with an older sister, the mistake was apparent, yet a close family likeness was noticeable. Among the individuals examined were the members of two Washington families, who for two generations have passed for white, but who, in the third generation backward, to personal knowledge, showed the light touch of Tubal. The children of the present generation are of light blonde type, with flaxen hair, and in facial conformity are more widely removed from their prototype than the number of generations would indicate. The iris is generally blue, and the sclerotic shows no pigment stains, such as may be observed in mixed blood, nor does the pigment layer underlying the sclerotic impart to it the transparent blue coloration characteristic of negro blood. The nails also are negative.

The Nose.—In the white races, without exception, the alar cartilages of the nose do not meet in the median line in front, but leave a considerable hiatus into which projects the cartilaginous portion of the septum naris. Further, the alar cartilages are sharply beveled, the interval being most marked at the apex where they project considerably beyond the septum. This may be felt readily by placing the tip of the finger against the tip of the nose. In the negro race the interval betwen the two lateral cartilages does not exist, the bevel is wanting, and the cartilages join each other so symmetrically that it is impossible to distinguish by touch that they are not one piece. It is this variation in the alar cartilages that gives to the nose of the true negro its breadth and to the mulatto's nose its rotundity. I make this lengthy mention since I recall no descriptive anatomist who has heretofore (1899) called attention to this fact. The peculiarity is fairly persistent, and, generally, may be recognized in quadroons, but fails to maintain itself in much diluted blood, and would not be recognizable when confirmatory signs, such as color, conformation of the face, quality of the hair, and odor are lacking. The upward tilt of the negro nose is shared by Tartars and other Asiatics. It disappears much earlier than the trait above described.

*State of Md. vs. Saunders (Howard Co.).

The Hair.—The hair of the negro, coarse, black, woolly and kinky. (Ethnol. "Ulotriches"), on closer examination presents noteworthy peculiarities. Hair of intense black color is found through a wide range of climates and races, such as American Indians, Chinese, Japanese, Jews, the races of India and almost all of the Latin peoples. In most of these, however, as the Asiatics and American Indians, the hair is straight (Ethnol. "Lissotriches"), although some Indian tribes show a waviness like a horse's mane. On cross section the hairs of the Asiatics and our Indians are found to be round and the cross section area fully twice the size of the average Anglo-Saxon blonde hair, and, generally, to show a central cylinder. The light hair of the Caucasians on cross section is seen to be ovoid and the central pigment cylinder is absent. The negro's hair on section is an elongated ellipse with very flat sides. Longitudinally it shows nodes or kinks at short intervals. This variation is one of the most persistent of the race and one of the last to disappear. In one case wherein I testified, the defense endeavored to establish the claim that the accused was of Indian descent.* Although none of the other general characteristics was quite sufficient to establish the contention that the man was of negro blood, yet the hair showed that he was not an Indian and allowed me to say that in all probability he was of negro descent. His mother, who was introduced by the defense to establish the Indian claim, was easily shown to be a negro.

Odor.—The odor of the negro is distinctive and is much more apparent in hot weather than in cold. The matter of its persistence is very variable and seems to be an individual rather than a racial characteristic. It is noticeable in the secretions of the genitalia long after it disappears as a general trait, but is too intangible to possess much value save as confirmatory evidence.

Osseous Variations.—The midpoint of the human body, measured longitudinally, is the symphysis pubis and in well formed individuals, male and female, is fairly constant, although, as pointed out by B. A. Gould, the length of the legs is, in man, one of the most variable points. In the negro, however, the symphysis is situated above the midheight generally, owing to the extreme length of the femur and tibia compared with the length of the spine. Further, our comparative measurements of the tibias and femurs in the two races show (*a*) that the femur very generally is longer in negroes than in whites of the same height, and (*b*) that compared to the length of the tibia the relative length of the femur is likewise much greater in the negro than in the white.

The stretch, *i. e.* the distance from finger-tip to finger-tip with the arms extended to their fullest possible length, in the white race usually exceeds the height of the individual, especially in males, by a small fraction. In negro males the stretch exceeds the height to a greater degree than in any other non-Caucasian race and is much greater than in the white race, four inches being not rare, and in one instance five and one-half inches was noted. These variations, however, soon fail as we depart from the true negro, and even in light skinned individuals have little significance. Many other osseous variations might be dwelled upon, as the greater length of the os calcis, the more pronounced development of the superciliary ridges, the general configuration of the skull, the tendency of the distal phalanx of

*State of Md. vs. Connors.

the great toe to project upwards—in fact, a score of others—but they are not pertinent to the purpose of the present article.

Pigmentation.—General pigmentation disappears quite uniformly with the approach toward the white race, but is prone to persist in certain localities where white persons likewise show unusual pigmentation. Such places are the nape of the neck close to the hair, the genital regions, about the orbits, and sometimes the cheeks. The nails will be described separately.

Pigment, likewise, is sometimes found in locations where it is not prevalent in white persons, as in the sclerotics, the schneiderian and other mucous membranes, in the cerebellum and the cerebral ventricles. Darwin believed that the negro's keenness of smell was correlated to the pigmentation of the olfactory tracts.

Upon the genitalia characteristics pigmentation sufficient to recognize the race persists very generally to the third generation, but thereafter is subject to great variation and uncertainty; nevertheless, when present, it is very positive evidence of negro derivation. A peculiar lentigo or freckling of the skin of the face and back is often observed in negroes of very light tint and dilute blood, particularly females. This consists of small, very superficial, round or oval flakes of pigment which appear strikingly superficial, seemingly as though flecked with a brush upon the epidermis. These spots are more regular and proportionally darker than the lentigo of the whites, being often the color of browned coffee. Upon the sclerotics, likewise, small points and blotches of pigment often are seen; the sclerotics frequently present a muddy, yellowish tinge.

Pigmentation being common to many races, is by no means distinctive, but in cases involving simply the question of negro admixture is distinctly trustworthy.

The Nails.—First, a few observations on the general character of the fingernail of the pure-blooded negro. In this race, as found in this vicinity, the nails are usually of coarse texture, showing frequent longitudinal striæ, but very generally showing the presence of well-developed, prominent crescents. Indeed, my observations would lead me to the belief that the crescents are not less frequently present in the pure black than in the pure white races, since I was particularly struck by the fact that in the lower orders of European races they were found frequently to be absent, especially among Poles, Hungarians, Hebrews, and Russians. The body of the nail often shows pigmentation by reflected light, and the darker hue of the underlying flesh gives it a dark, dusky color, varying from brown to bluish-purple. The matrix is tightly adherent and on its upper surface, with the exception of a few longitudinal fissures, is continuous with the epiderm.

When, however, we examine the mixed races, we are immediately struck with a marked peculiarity, namely, the very general absence of the half-moons. This peculiarity shows itself as soon as we depart from the true negro and is markedly true of individuals who might be classed as mulattos, quadroons, and octoroons. In those of still more attenuated blood we get a gradual return of the lunette, which return bears a pretty constant ratio to the attenuation, and therefore serves as a fair index of ascent in the scale toward the white race.

It recurs first on the thumb, where it is often found with considerable admixture of dark blood; next, it is found most often on the little finger, and then on the index finger, after that, perhaps on the middle finger, occurring numerically oftener in the individual, as has been said, as the admixture of dark blood thins. Likewise the two hands are more frequently in harmony in the more blood-attenuated individuals. This description applies to those individuals in whom the admixture of negro blood is unmistakable and in whom it is plainly apparent owing to pigmentation and physiognomonic markings, and in whom therefore the traits enumerated, while interesting as variations, do not bear directly on the proposition. Moreover, in this class, the body of such nails, by reason of pigmentation between or beneath the layers could readily be recognized by a practised observer as belonging to a colored person.

As intimated, the flesh beneath the negro nail is dark in color, often of a bluish or purplish tinge, thence varying to the dusky color of lean ham. Especially is this color recognizable beneath the lunette. Further, it is quite true that the semi-transparency of the lunette and the underlying coloration described often persist to an unusual degree of mixed descent, recognizable very generally to the third generation, but not always. On the other hand, it is recognizable in the fourth generation with the utmost rarity, and therefore, of little, if any, value beyond the third generation.

The principal interest naturally centered in the examination of individuals whose features and color did not stamp them as of negro descent, but who admitted or were known to have contaminated blood in their veins. A careful examination of a large number of these, utterly failed to reveal any distinctive markings which would designate the "pariah."

The experiment was made a number of times of covering such persons and allowing the students who had assisted in the work to guess whether the individual were white or colored, the nails alone being exposed. It is to be noted that in a number of the cases herein referred to, the general racial traits were so far absent that critical examination did not enable me to classify them correctly. Especially was this the case with young children and with males more than females, which might be accounted for on the grounds of sex selection.

In conclusion, I express my belief that there is no positive sign whereby a very attenuated strain of negro blood may be asserted, the prevalent idea to the contrary notwithstanding.

1321 North Charles Street.

THE AFTER-CARE OF DISCHARGED CASES OF PULMONARY TUBERCULOSIS.*

By ALFRED MEYER, M.D.,

NEW YORK.

Let me state this problem a little more broadly: What shall be done *with* or *by* the large number of patients suffering from pulmonary tuberculosis who have been discharged from institutions, and how can the interests not only of the patient but also of his family and of the community best be served?

The problem varies somewhat according to whether a patient has been discharged with the hopeful labels of "apparently cured" or "disease arrested," or the less hopeful one of "improved," or, worst of all, "unimproved," which almost always means "worse."

"Apparently cured" and "disease arrested" cases

*Read before the Third New York City Conference of Charities and Correction, May 8, 1912.

most frequently return to the wage-earning class, as do a good proportion of the improved. The remainder are unable to do so and must either join the ranks of the rounders who are provided for by institution after institution until death, or they remain at home, a menace to their surroundings always, and all too frequently a focus of infection for other members of their family. This aspect of after-care is well illustrated in a study made by the National Council of Jewish Women. Three hundred cases of all stages discharged from Raybrook, Otisville, and Bedford Sanatoria during a period of five years were investigated. One hundred and thirteen, that is, over 37 per cent., occupied rooms with other members of their family, and 42, over 13 per cent., did not sleep alone. In another series of 361 at home cases reported by Miss Crowell for the Association of Tuberculosis Clinics, over one-fifth of the cases were sharing their bed with another member of the family.

In any systematic plan in our city for dealing with discharged cases the first and most important step is to provide a great increase of hospital beds for the advanced and far advanced cases. The State Sanatorium at Raybrook does not keep such cases longer than nine months; Otisville is not expected to keep them, and Bedford gives them a year, but then refers them to the Montefiore Home in the city, or to the inadequate care of their relations. In numerous instances the patients are too sick to travel and the sanatorium is forced to keep them until relieved by death. This often, unfortunately, means the occupancy for many months of beds established for the care of incipient and presumably curable cases that were ultimately to return to the wage-earning class. The needs of New York City with regard to hospital accommodation for such cases and the almost inhuman inadequacy of the present provision is well presented in a report issued by the Tuberculosis Committee of the Charity Organization Society in June, 1911: "A careful study has been made of the whole hospital situation, and it has been estimated on the basis of figures at hand that we need at once between 6,500 and 7,000 tuberculosis hospital beds, nearly 4,000 more than we now have."

Under these circumstances it is quite natural that physicians and philanthropic workers have been looking forward eagerly to the completion of the Sea View Hospital on Staten Island with its more than 1,000 beds, the largest single antituberculosis undertaking by the city since the agitation and crusade against this disease began. There is a horde of people awaiting care at such a place—people who have been at different times in charge of sanatoria, hospitals, and tuberculosis clinics. The eagerness is tempered with a feeling of regret that over six years have passed since the initial appropriation was made and the institution is still unprepared for the admission of patients—six years full of delays, some avoidable, some unavoidable, not creditable to our city government when compared with similar undertakings by private citizens.

Such institutional after-care for the presumably incurable cases is the one to be urged from the point of view of patient, family, and community until death relieves the patient of his suffering and the family and municipality of their responsibility. Unfortunately a considerable minority of such cases, for reasons of a domestic nature, prefers to remain at home. For them the opening of the East River Homes ought to prove a great boon. From the point of view of the home care of tuberculous patients nothing has happened in recent years in New York City to compare with this in importance. It is a well thought out and well executed plan for the humane housing of these unfortunates. It needs only a fuller acquaintance with them on the part of the medical profession and the people to get the needed cooperation which will make for the ultimate success of the scheme.

An important need in the after-care of arrested or apparently cured cases is a periodic reexamination of the patient, say, every three or four months, irrespective of how he feels or what he thinks. The plan is certainly feasible for tuberculosis clinic cases, and they form the major part of cases in New York requiring public care and supervision. Relapses might be diminished in frequency and extension of the disease more promptly recognized. For cases discharged from out-of-town institutions this would not be so feasible.

An increase in the number of women's auxiliaries connected with the tuberculosis clinics would also appear desirable. There are only nine such now in existence, whereas the clinics number twenty-three. When all is summed up that is being done by various agencies in the after-care of discharged cases, the lamentable fact still remains that many relapse because they are compelled to return to the unhygienic living and working conditions in the tenements of our cities. Thus as the Bedford Sanatorium of the Montefiore Home in the nine years 1902 till 1911, 153 men were readmitted with relapses, and four of these were admitted a third time. Similar experiences are reported by tuberculosis institutions and workers all over the world. Thus in a recent report of the Charity Organization Society Tuberculosis Committee prepared by Mr. Mann it was shown that there were 1,688 cases of homeless patients admitted to hospitals for the second, third, fourth, fifth, or more times in the fifteen months ending March 20, 1912. I do not know to what medical classification they belonged.

The time seems ripe for the introduction of another factor into the after-care of apparently cured and arrested cases, and that is the establishment of industrial and farming colonies. This is not a new idea; it has been advanced by many writers in different countries, but very little practical headway has been made anywhere. A few small farm colonies have been established; nothing has been done along industrial lines. Thus Dr. Philip of Edinburgh, after many years of endeavor to create public opinion, finally succeeded two years ago in establishing a 50-acre farm at Springfield, seven miles from Edinburgh, for arrested cases from the Royal Victoria Hospital. Another small post-sanatorium farm colony is operated successfully at Sannum in Oldenburg, Germany; in Norway, Sweden, and Switzerland the matter has scarcely progressed beyond the point of suggestion and agitation.

In our own country the experiment has been tried on a very small scale by the Eudowood Sanatorium, Md. It purchased a tract of land adjacent to the institution and eight men and boys who had been discharged were put to work raising hay, corn, and tomatoes. Wages were given. It is claimed "that this is the first attempt in this country to provide those leaving a sanatorium with work in a field where they may be able either partially or completely to support themselves under such guidance and in such favorable surroundings that the cure they have made is likely to become permanent."

The idea is really an extension to the patients *after* discharge of the method of work under supervision which already prevails in a number of our American Sanatoria. Thus Dr. Biggs says of Otisville, "that it is the policy to administer the institution as largely as possible through arrested cases—work is provided for a considerable number and experiments are being undertaken to build proper houses for such employees and their families and actually to supervise all the conditions of life of these ex-patients and their families even as if they were still inmates of the institution." Similarly at Saranac Lake, Trudeau has started a workshop at an outlay of between seven and eight thousand dollars. At times as many as fifty patients are engaged here in a great variety of occupations: carpentry, cabinet and all sheet metal work, typewriting, lace work and lace loom manufacturing, printing, illuminating, bookbinding, photography, framing, glass and leather work. The teaching staff consists of one superintendent and two assistants. At the Bedford Sanatorium for some years small individual truck gardens have been worked by about 75 patients, including children, under the guidance of a paid graduate of an agricultural school.

Enlarging then upon this idea I would advocate the establishment of farming and industrial colonies by one of the following methods: either as annexes to existing sanatoria, one at Raybrook under State control, one at Otisville under municipal control, one at Liberty, one at Bedford and one at Stonywold; or by the establishment of such colonies as independent undertakings, by public and private philanthropy apart from pre-existing institutions.

Of the two methods I prefer that of annexes to existing institutions for the following reasons:

It will be easier to get the patients to remain because of familiarity with their environment and because of restoration to health at that place.

It will be easier to prepare the way for the settlement of other members of the family in the same community during the last weeks or months of sanatorium care, and pending discharge.

It will be easier to acquire land for factories and farms because communities where sanatoria already exist would not oppose their establishment, for they haven't the phthisiophobia prevalent everywhere else.

It will be easier to enlist the aid—both by counsel in the developing stage and by guidance and supervision in the fully developed stage—of many medical men who have been most enthusiastic in the tuberculosis campaign. The same applies to the volunteer boards of lay people now administering some of these institutions.

It will avoid much of the delay that would be caused by hunting for new sites and a discussion of their general availability for the care of convalescent tuberculosis cases.

It may prove easier to obtain financial aid from state, municipal, and private sources as an extension and evolution of the humanitarian work already undertaken by them, rather than for the initiation of an entirely independent scheme.

The possibilities of industrial colony development apart from pre-existing institutions or communities are illustrated by the work done at Woodbine, N. J., under the auspices of the Baron De Hirsch fund. This colony was started twenty odd years ago for the benefit of Russian Hebrew immigrants. It is now a well-ordered, self-governing community of between 2,500 and 3,000 souls with model streets, homes, schoolhouses, and factories. Lots were sold on easy terms, mortgages being gradually paid off and not more than two families permitted in one house. The industries include manufacturing of clothing, hats, sweaters, machines, and yarn. The farming aspect has been less successful, but for easily explained causes avoidable by similar undertakings in the future.

Of course the illustration is not perfect (What illustration is?) because the Woodbine colonists were not convalescents from tuberculosis. But at least they were handicapped in many other ways—driven from home by religious persecution, settling as involuntary colonists in a strange land, among strangers, speaking a strange language and encountering customs and manners equally strange; still they have found a foothold on the soil, and are rearing their children—yes, and already their grand-children—among conditions that permit the rational pursuit of health and happiness.

Although I prefer the annex idea for the reasons already mentioned, still I must admit that the State has given an example of success by the alternative plan in dealing with another disease. I mean the colonies for epileptics and feeble-minded at Sonyea and Letchworth Village.

In this paper I have not considered at all the question of the care of the vagrant and alcoholic cases, whose number has been proved to be very great. For these I would favor compulsory segregation, and the suggestion to use Riverside and the Metropolitan Hospitals for this purpose seems a good one.

I am well aware that I have advocated a plan for the enlargement of tuberculosis work in this community which is colossal, and which will require great sums of money, and the thought and energy and enthusiasm of many workers for years to come. I agree with Dr. Gulick that in public health matters *what* to do is a medical question—*how* to get it done is a social question; a problem for the social engineer.

785 Madison Avenue.

THE INSURANCE EXAMINER AND BLOOD PRESSURE TEST.

By FRANCIS ASHLEY FAUGHT, M.D.,

PHILADELPHIA.

INSTRUCTOR IN MEDICINE, MEDICO-CHIRURGICAL COLLEGE.

For some years now it has been recognized that the blood pressure test is a useful and important guide to the state of health, and that in some cases when an individual may appear to be perfectly normal this test may give most reliable information. By it we may detect the signs of beginning change in the cardiovascular system and the kidneys, often before there is any distinct evidence of departure from normal, either in the physical signs, personal history, or uranalysis. In some cases we find that the apparent character of the pulse and a study of the superficial vessels fail to convey the proper impression of the state of the vascular system. That the arteries may not be what they appear, that the heart has become hypertrophied, or that a cerebral hemorrhage may at any time occur in spite of an outward appearance of perfect health.

The estimation of arterial tension or blood pressure by palpation is most unsatisfactory and at best unreliable. Even the most experienced clinician finds it very difficult if not impossible to estimate blood pressure accurately by palpation of the radial.

To quote from Wm. Russell (Arteriosclerosis, Hypertension, and Blood Pressure) we find the following very significant statement: "I must, however, again add a warning note to the effect that—feeling the radial pulse is not always a reliable guide as to what the blood pressure will read—I have two such cases under observation, the radial in neither being hard nor incompressible, and yet in both there is a steady reading of over 200 mm. of Hg."

Many times we may feel a soft and compressible radial where there exists marked sclerosis of the aorta and of the splanchnic area. Here only the blood pressure test reveals the true situation. In other instances the reading of the sphygmomanometer may explain the significance of an apparently simple headache, a mild attack of indigestion, transitory attacks of vertigo, in an apparently healthy individual, by demonstrating that these cases have suffered from a long continued toxemia, which has resulted in an unsuspected pathological change in the cerebral or other vessels.

It is now well recognized that such pathological changes may be present in the cardiovascular and renal systems, long before any suggestive symptoms are complained of by the individual, or if any complaint is made it is usually attributed to some trivial cause.

In the presence of such a beginning arteriosclerosis the blood pressure need not be greatly increased, an elevation of 30 to 40 mm. above that estimated as normal for the individual is significant and demands explanation. On the other hand a rise of even this amount should never be hastily assigned to arteriosclerosis and the risk therefore rejected without further study.

It is necessary to recognize in this connection the activity of other and less important factors, such as the alimentary hypertension, so well described by Russell, occurring in normal vessels due to errors in diet of either quantitative or qualitative origin and responding immediately to the correction of such errors together with stimulation of the eliminative functions. Of further interest particularly to the life insurance examiner are the so-called physiological variations, caused by age, sex, mental and physical excitement, fatigue, etc. These must all be taken into consideration in estimating the character and class of the risk.

Such variations need not confuse the examiner, as they all occur within a range sufficiently restricted to prevent them from obscuring the issue. The only one which needs special consideration is the age factor. To determine this, many tables have been suggested and devised in an effort to indicate the normal average systolic pressure for any given age. While these agree and can be applied, they are difficult to employ and hence are unsatisfactory, as their use entails reference to a table or the carrying of many figures constantly in mind.

To simplify this, the author suggested a formula based upon a large number of observations of his own and of others, which could be universally applied. The average obtained by this formula agrees closely with the experience of most observers, and since its first publication in 1910 (The Sphygmomanometer and its Practical Application, Pilling Co., Philadelphia) has been extensively quoted and is now employed by at least one insurance company (the Providence Life and Trust Company, Philadelphia). As originally suggested, it was as follows: "Consider the average normal systolic blood pressure in the male at age 20, to be 120 mm. of Hg.; for each year of life thereafter add one-half millimeter to 120." Later it seemed advisable to eliminate the fraction and this was done by changing the phraseology to read as follows: "Consider the normal average systolic blood pressure of a male age 20 to be 120 mm., then add one millimeter for every additional two years of life." In both the formulas the practical result is the same; thus at age 30 the normal average systolic blood pressure would be 125, age of 60, 140 mm., etc. It is sufficiently established to pass without question that the normal average blood pressure for women is approximately 10 mm. less than for men of the same age.

It is not sufficient to establish a normal average with which to rate the risk, but it is necessary to determine what variations above and below this shall be permitted to pass as normal. Unfortunately, with the evidence at hand, this question cannot be definitely answered, as existing statistics do not agree. So far as can be gathered from many published reports of the blood pressure test, a range of pressure of 35 mm. is deemed not to exceed normal. If we accept this, then a variation of 17 mm. above or below the normal average may be allowed; thus at age 20 any reading of over 137 or below 103 would call for explanation, while at age 60, the permissible variation should lie between 157 mm. and 123 mm.

In all determinations of blood pressure, the factor of the diameter of the cuff employed, and the type of instrument used in making the test, must be considered, assuming, of course, that the accuracy of the instrument itself is not disputed.

At the present time the accepted standard for the width of cuff is between 4¼ and 5 inches (11 to 13 cm.). A narrower cuff gives readings proportionately higher as the cuff is narrower.

Only those instruments that are in general use will be mentioned here. Among the mercury instruments employing the standard cuff, may be mentioned the Faught Standard, Cook's modification of the Riva Rocci, the Pilling Special, Kny Scherer, the Stanton and the Martin (in England) and among the aneroid the Faught Pocket Indicator. The Riva Rocci employs a narrow band and gives readings that may be from 15 to 50 mm. too high. Gaertner's tonometer gives readings which range from 10 to 20 mm. too low. The instrument of Potain is not graduated in mm. of Hg. at all, and therefore cannot be directly compared with the results obtained by other instruments. Potain in his work on blood pressure gives the normal for man, with his instrument, as 150 to 190 and in women 140 to 180 (Potain "La Pression artérielle de l'homme a l'état normal et pathologique," 1912).

As a routine measure, the left arm should be employed and bared to permit application of the cuff. Both applicant and operator should be in comfortable position, preferably sitting posture; nervous individuals should be assured of the harmlessness of the test, and should have their attention diverted from the proceeding. Time also should be allowed to permit the circulation to become quieted, after such exercise as rapid walking, stair climbing, etc.

When there is any doubt as to the accuracy of his finding, the operator should see the applicant upon a subsequent occasion, before making his report.

Bearing in mind the difficulty of early diagnosis in a case of chronic nephritis by a single uranalysis, particularly in individuals of apparently normal health, the importance of a blood pressure test will

be apparent, because it is recognized that we cannot have permanent kidney change without a constant elevation in blood pressure, and even in the presence of albumin or casts, we may question their true significance. Here a persistently high blood pressure, say 150 mm. or over in an individual below middle age will settle the question at least in regard to the risk. The presence of albumin and casts appearing scantily in the urine is not conclusive evidence of a diseased kidney, as these elements may come from a number of transitory and comparatively unimportant conditions. The blood pressure test will serve as a check, so that the applicant with a normal blood pressure which has occasionally shown albumin and casts will not immediately be rejected. In future such individuals may be given the benefit of the doubt and the company thereby relieved from committing a grave injustice. Besides the physiological variations already mentioned, the examiner employing the blood pressure test must endeavor to control as much as possible the condition surrounding the observation, otherwise the data as forwarded to the home office may be misleading. Every effort should be made to find out what is the actual blood pressure of the individual. More than one observation should be made when necessary in order to avoid reporting an abnormally high pressure, influenced temporarily by emotion, violent exercise, digestion, posture, or alcoholic stimulation.

A class of individuals demanding careful consideration by the insurance examiner is the overweights. This group does not show a favorable mortality in insurance statistics, particularly in the higher ages. Very often we may make our final decision in the moderate overweight on the blood pressure reading, accepting doubtful cases when it is normal, and declining if there is a tendency to high pressure.

The presence of a myocardial degeneration must always be considered, since the usual methods of examination rarely demonstrate the incipient cases of this affection. Difficulty will not be encountered, of course, when the disease has progressed sufficiently to affect the general health of the individual. In the early cases the systolic pressure need not be materially affected, so that recourse must be had to the functional tests of Graupner and Shapiro, and to the diastolic and pulse pressure, by which changes in normal reserve of the heart the strength and volume of its output can be estimated. Regarding the question of diastolic and pulse pressure there is but little definitely known, although several conditions are now recognized as affecting these readings which can be applied in health examinations and used to advantage in the work of the insurance examiner. Thus arteriosclerosis, on account of diminished elasticity of the blood vessels, will show an increased pulse pressure (over 35 mm. above the average) and the more extensive this change in the vessels the greater will the pulse pressure be. This condition may be demonstrated in a suspect even before the systolic pressure has permanently passed the normal high limit of health.

In incipient tuberculosis the only evidence of this condition besides possibly a slight rise of pulse rate and loss of weight will be a hypotension or subnormal blood pressure, usually accompanied by a diminished pulse pressure. In this connection Haven Emmerson (*Archives of Internal Medicine*, 1910), stated that hypotension is found in almost all cases of moderately advanced tuberculosis and that it has been found by many observers in early doubtful or suspected cases with or before physical signs of the disease of the lungs, and that it is considered by competent clinicians as a most useful sign. Cook also states that low blood pressure if persistently found in individuals or in families should put us on our guard for tuberculosis. In applicants of lightweight and a blood pressure of 100 or under and of poor family history the risk is bad.

Such mortality statistics as are available upon the relation of the blood pressure test to insured risks and their cause of death, bear witness to the importance of universal employment of the sphygmomanometer in life insurance work. The most important contribution to this study comes from the pen of J. W. Fisher of the Northwestern Mutual Life Insurance Co. (MEDICAL RECORD October 21, 1911) which covers an extensive study beginning in 1907. From a study of 2,668 insured taken from the actuary's tables giving blood pressure readings between 140 and 149 mm. Hg. he had 81.85 expected deaths, with 31 actual deaths, a percentage of 37.87 which was slightly below the normal death rate of the company on exposure of two years. He shows another table of mortality record of 527 insured persons with a blood pressure reading of 150 mm. Hg. and over, with 22.19 expected deaths and actual deaths were 12, which is about 35 per cent. in excess of the general average mortality of the company covering the same period and 18 per cent. higher than the general average mortality during the first five years of exposure covering the 20-year period of 1885 to 1905.

In table six he shows a mortality record of 782 persons, declined for insurance, in whom the blood pressure averaged 171.03 mm. Hg.; 21.61 deaths were expected with 32 actual deaths, a percentage of 155.27 or almost four times greater than the general average of the company. In another table he shows 366 cases rejected in which there were reported no other impairments than high blood pressure at the time the application was received at the Home Office. The expected deaths were 10.14, the actual deaths 14 or 138.17 per cent. of the table. Efforts were made to carefully follow these 366 cases in order to secure data as to the subsequent physical condition of these applicants. This is best shown in Table No. 10 of the article here referred to, which is copied in full.

TABLE 10. Subsequent Impairments Discovered or Developed; 366 Cases Rejected with High Pressure Only.

Arteriosclerosis Atheroma	Heart Murmur	Heart Hypertrophy	Albumin and Sugar	Albumin Only	Sugar Only	Albumin and Casts	Casts Only	Nervous Symptoms	Miscellaneous	Total	Expected	Actual	Per Cent.
6	9	4	2	14	5	33	13	6	10	101	3.061	4	130.66

These statistics are ample to show the great value of this test to Life Insurance Companies and also to show the almost absolute confidence which can be placed in a correctly made blood pressure record without even considering the other factors of the case.

The study of blood pressure in Life Insurance examinations has not yet met general acceptance by the Insurance Companies, although each month adds to the number requiring the test at the hands of their examiners. In some cases the blood pres-

sure tests is now employed in the examination of every applicant, irrespective of age, weight, past personal history, or amount of insurance applied for.

The chief drawback to the universal application of this test by Insurance Companies seems to be the difficulty presented by the examiners themselves who have been slow to see the advantage of the study and the use of the sphygmomanometer in their practice.

The recent rapid advances of sphygmomanometry will undoubtedly speedily overcome this objection so that in the near future this test will be incorporated in the printed form for the routine examination of every applicant for Life Insurance.

5231 Baltimore Avenue.

RACE RESISTANCE.

By HORACE GREELEY, M.D.,

BROOKLYN, N. Y.

A good deal has been written and said about family tendencies to disease; indeed the belief is popular that maladies are actually inherited, while little thought is given to those national weaknesses which every distinct people, as but a larger family, undoubtedly manifest. Of course, many of our modern nations are too conglomerate and recently formed to possess such peculiarities to a recognizable extent, yet many distinct races with which we are familiar may be shown to manifest either greater susceptibility or more resistance than the average to many common adverse conditions and maladies.

In the first place possibilities show that this may be either in the direction of mechanical wear and tear, the endurance of the organism as a machine, or the possession of those latent forces whose elaboration determines the result in diseases due to parasitic agencies. As illustrative of the first, a race may possess heavier and stronger bones than another and therefore be less subject to fractures; a skin more suited to the sunlight intensity of its locality; muscles better able, with the least strain, to overcome the physical resistance of the daily routine and stronger and more resistant teeth with all the possibilities of more efficient digestion following. Also many minor physical peculiarities which may render their possessors better able to compete under those natural conditions, as modified by civilization, that ever make for the survival of the fittest.

Negroes have proverbially heavy and tough bones, not only of the skull but throughout their framework, and comparatively seldom suffer from fractures. The same is true of their teeth which, while exposed to all adverse conditions, show considerably greater endurance than in most races. Among the white peoples the Teutons claim first advantage in these particulars, as also in muscular endurance, although this is really entirely dependent, apart from conditions of disease, upon the food supply. It seems that the color of the skin is only of concern in tropical regions where the demand for protection against the harmful effects upon all tissue activity and growth, similar to that exerted upon bacteria, of too strong a sunlight, requires a more impervious screen than the blond skin of the northern races, so that here the darker complexions have the advantage.

But it is with the second that our chief data are concerned, and corroborated as they are by all that we know of the principles of immunity make very interesting and important matter. The Jewish race has been known for at least five thousand years, and according to every conservative indication has remained a practically pure racial stock for that time, and during the last two thousand has been almost entirely a city dweller, usually amid the most crowded and unsanitary conditions, and yet today, in spite of a physique and appearance much under the par of the average population, its individuals are both longer lived and more resistant to all the infectious diseases than any other member of society. The last United States census gave the comparative number of deaths for the year among each one thousand of the living members of the principal races in this country as follows:

From All Causes.

Ages.	Native White.	Colored.	German.	Irish.	Scandinavian.	Italian.	Jews.
0-4	43	118.5	47.6	56.1	37	80.7	36.7
5-14	3.7	9.8	3.7	4.5	3.7	4.9	2
15-24	5	15.6	4.8	7.5	5.7	6.6	2.7
25-34	6.4	16.9	7.4	12.2	7.4	7.1	3.5
35-44	7.5	21	9.6	15	9	9.2	5
45-64	14.6	36.7	20.3	30.6	16.9	17.2	9.7
65-	65.9	108.6	81.8	96.9	67.3	66.1	40.9
From Consumption (Per 100,000 living).							
0-15	27.5	246	26.6	42.2	32.4	50.7	11.4
15-44	162.5	587.4	205.9	428	233.7	149.9	67.4
45-64	131.8	518	207.5	340.9	267.3	157	103.9
65-	176.4	548.7	235.3	324.7	236.6	144.7	243.2

A glance at this table will show the immense difference between the mortality of the Jews and that of all other races. Even the native whites, who undoubtedly live under better hygienic conditions than any of the others, have a rate greater by fifty per cent. On that best basis of comparison their resistance to tuberculosis, the disease of all others to which the whole population may be regarded as universally and constantly exposed, they show a mortality of less than half that of the native whites except beyond the age of forty-five, before which period, as is apparent from the table, the greatest death rate exists among the more susceptible races. After this age the Jew's comparative mortality from this disease rapidly increases and, after sixty-five years, surpasses that of any other white race for the reason that they are so resistant to the malady that when they do succumb it is much later in life. It is known that the most congested districts of a city have the heaviest death rate, and to bring out the great resisting power of the Jews to the concentration of the health menacing factors of modern civilization here present it is interesting to note that in the most thickly populated sections of New York and of Chicago their death rate from tuberculosis is but 1.63 per thousand living, while the Gentiles under the same conditions suffer to the extent of from 4.95 to 5.65, fully five times as much. In Berlin this rate is: Jews 1, Gentiles 2.17; and in Vienna 1.31 as compared to 3.17.

The Irish, mainly descended from the ancient Celts that peopled all of northwestern Europe, have until recent years been an isolated and rural people and have not developed, because not stimulated to do so by circumstance, that resistance to transmissible disease that has been forced upon the city dweller. Previous to 1864, when the urbanization of the country practically began, Ireland had the lowest death rate from tuberculosis of any portion of Europe, but since this period the rate has steadily risen until at present it equals sixteen per cent. of all deaths as compared with England's rate of nine per cent. and the United States' of ten and a half. This shows how markedly resistance depends upon exposure, for while the disease undoubtedly was carried to Ireland by the original Celtic settlers their isolation and lack of intercommunication impeded its spread until recent years when, in addition to

changes due to the greater development of the cities and improved methods of travel, the frequent return of the emigrant, when sick, to his native heath increased the last, the opportunity to acquire, without the malady's greater prevalence having had time to raise the former, the resistance. In the United States, as will be seen from the foregoing table, the Irish lead all the white races in this sinister particular, even showing during the age period of fifteen to forty-five a comparative rate of more than double any other, besides being far in the lead in the table showing deaths from all causes.

In Italy changes similar to those in Ireland have occurred and the tuberculosis death rate in the more modernized and commercial provinces of the north has risen accordingly till it is at present double that of the southern more rural and backward portions. In the province of Milan, for instance, the rate is 3.20 per thousand living, while in that of Messina it is but 1.60. The best authorities state that fully one-third of all Italian emigrants under twenty-five years of age coming to the United States (although all are carefully inspected before entering this country and detected cases debarred) eventually die of tuberculosis, and it has been claimed that a fourth of those returning in the steerage are suffering from the disease.

In the United States, as may be seen from the first of the foregoing census tables, the Italian death rate, except for those under fifteen years of age, is about the same as that of the other foreign nationalities represented, not considering the Jews or the Irish; but in the second table covering the tuberculosis factor alone the Italians lead the remaining white races. This apparent special susceptibility of their children, while partly actual and due to habits of feeding induced by poverty and economy which render them more than others the prey of general disease, is in a great measure to be explained by the immense reduction in the mortality lists of the adults resulting from the return of the latter to their birthplace so soon as they become seriously ill, which is effected either on their own savings, through their government's representative, or with the assistance of a benevolent society. The resistance of the other Latin races is of a similar nature and degree.

The German death rate from all causes, in this country, is but little above that of the natives, more markedly so from tuberculosis—see tables—while in regard to the somewhat modern and increasingly prevalent cancer it leads in the returns, as follows:

Ages.	U. S. White.	U. S. Negro.	German.	Irish.	Italian.	Jews.
Under 65	155.3	159.1	238.6	232.2	119.4	92.3
Over 65	374.9	290.6	561.5	479.9	392.7	263.5

The rate from this cause is next greatest among the Irish, as of common Celtic stock; it is lower among their more distant relatives, the Italians, and among the negroes, the furthest removed and most distinct variety of the human family, the rate is only second to that of the Jew. These relative susceptibilities are maintained by European statistics, and all show this disease to be on an apparently world-wide increase.

The Scandinavians, another Celtic offshoot, seem to have tendencies similar to the Irish, modified again by special conditions, for they have almost as little resistance to tuberculosis, having second place in the table of European death rates from this disease at 1.92 per thousand as compared to that of the Irish at 2.16. In this country they also follow close upon them, as will be seen in the returns from the city of Minneapolis, largely settled by the former, where the death rate from this malady per thousand living is: Foreign born Scandinavians, 1.69; native born of such parents, 1.14; as compared to the rate of 0.69 of those born of American parents, thus clearly showing that this national trait is being modified as the Scandinavians become more and more lost in mongrel America. In regard to leprosy, it seems that among the Scandinavians alone of all the European races this disease is increasing, undoubtedly owing to some peculiarity of constitutional make-up by which the Scandinavians have lost their measure of European immunity to this old-time malady.

Coming to the Japanese, as representative of the second great leading variety of the species, the Mongolian, and first to the discussion of what has been delayed till now, the supposed varying ability of different races to perform a given work and maintain a body equilibrium on a minimum diet, as this is the people credited by some with the special ability to produce the most under such conditions. It is a well known and publicly recognized fact that anyone on a daily diet of beefsteak, changing to fish or fowl or even mutton, frequently experiences a digestive revolt which is popularly attributed to a poisonous quality peculiar to the particular article, or to a permanent idiosyncrasy of the consumer. The same is true as regards almost any unaccustomed food. The true reason of this, as determined by physiologists, is that each and every substance in use as food presents to our digestion particular and special poisons with which, if unprepared by previous and prolonged experience, it is unable to properly cope and the symptoms of intoxication naturally result. So it is that anyone, no matter how poisonous to him any particular food may at first seem, may be gradually accustomed to its use, as special antitoxins necessary to counteract its injurious influences are gradually elaborated.

The little Japanese has for generations lived principally upon a vegetable diet (rice) which, although it supplies almost a minimum of tissue building material, contains everything necessary for driving force and when once the digestion has been accustomed to handling it, it is easily made to fulfill all requirements—the over-supply of starch becoming tolerated even if not all used—so that if he is able to accomplish more on a unit of this simple food than a European, it is the result of a prolonged course of ancestral and individual digestive education which would have produced the same result in another. The Italian laborer on bread, maccaroni, and a little "lardo," is a similar example of accustomed diet which enables him to do the very heaviest work, although at a great cost to his machinery, which is worn away rapidly without the greater reparative assistance that a more liberal diet supplies. With this we will dismiss racial claims to superior endurance under privation and physical strain, for no test would be fair that did not allow to each the conditions to which it was accustomed, and when these are permitted all are alike. So, as the Japanese are passing under what are best denominated modern commercial conditions, their death rate is rising, especially from tuberculosis, which now causes almost twenty-five per cent. of all deaths as compared to a Caucasian average of fifteen per cent. and this, for reasons similar to those explaining the increase in Ireland. A like reasoning applies to all claims for racial longevity as dis-

tinct from special susceptibilities as detailed, for this depends principally upon the conditions of food and work affecting the individual, particularly as to whether they are his normal conditions.

In 1822 the death rate of the negroes in the United States equaled that of the whites, forty per thousand living; but since slavery's abolition and the changed conditions of life among them it has rapidly risen to seventy, nearly double, while that of the white population has almost halved. Today the negroes share with the Indians and others of recent savage ancestry a great susceptibility to infectious diseases, notably tuberculosis, and a glance at the census tables shows how enormously their death rates are ahead of all others included therein. In some ways, however, the negro has greater resistance than the white man, namely, to malaria and yellow fever (both caused by organisms of allied nature), to which special immunity is so lacking among the Caucasians that that of the negro becomes markedly impaired in the mulatto.

The so-called savage races present a great contrast by which we may judge of the resistance to the diseases of civilization already acquired by the white man. The American Indians when first seen were free from most of our infectious maladies, and therefore unarmed against their attack, and so great is their present susceptibility to, for instance tuberculosis, that fully seventy-five per cent. of all deaths among them, even those on Government rations and leading idle and even temperate lives in the so-called best climates, are caused thereby. Among the Sioux twenty-five die yearly out of every thousand living, while among the same number of Jews only 0.7, and the same number of Irish, 3.4 succumb. In passing it may be noted that most of those Indians who do not die of this malady yield to heart disease, a fact rather negativing suppositions that such is ever caused by overwork. So great is the Indians' lack of resistance that in certain French-Canadian settlements, where many have partial redman ancestry, tuberculosis is found to be as virulent almost as among the full-bloods. Again those Indians, as the Pueblos, and those in Mexico that have long resided in villages, show much greater resistance to the malady, having already been exposed long enough to the evils of the white man to have developed considerable immunity. Among all of the uncivilized, all over the world, passing under modern conditions imitated from or imposed by Europeans, together with greater exposure to cases of the disease, tuberculosis is so rapidly increasing that it, more than any other factor, promises to make this an entirely white man's world, a suggestion that, despite all the influence of civilized modern methods, natural selection is ever dominant, making for the survival of the fittest.

Most of the contagious diseases of childhood, with which civilization has been afflicted since time immemorial, have become so unable to effect harm that although nearly every child exposed contracts them a fatality is most rare. That this is due to immunity gradually acquired by transmission of an ever-increasing resistance from parent to child is borne out by the disastrous effects of these same maladies among savage nations, as the Eskimos, Hawaiians, Maoris, the Hill Tribes of India, or the inhabitants of Polynesia where an epidemic of measles, whooping-cough, or influenza, will destroy in a few weeks half the population of a village. In 1875 an epidemic of measles in the Fiji Islands carried off within four months, fifteen thousand out of a population of forty thousand. In South America and Mexico and the West Indies soon after the discovery by Columbus, the major portion of the native Indians were destroyed by such diseases, and today their remaining representatives, and even those having a detectable Indian strain, are particularly susceptible to them. Our old Biblical enemy, leprosy, evidently with our ancestors for ages, and now diminishing to almost extinction among all white races except the Scandinavian, has found a more suitable soil with these unsophisticated peoples and seems to be gradually increasing in prevalence among them.

Thus the degree of resistance any race presents may be shown to be directly proportional to what may be called its natural education to the requirements of the surroundings, and it is a matter of common knowledge in the tropics, and even in the cities of the temperate zone, that newcomers are more apt than natives to fall victims to any prevailing disorder, so showing that residence for a few years even may increase individual resistance to a recognizable degree. So it is easy to understand how constant exposure of a particular race to a particular disease produces constantly increasing immunity, as those who in the beginning possess it to the greatest extent outlive the others, transmit to the greatest number of offspring some of their protection, which in its turn is exposed to similar trial, possible increase, partial transmission and restimulation, and this is repeated progressively down the ages till quite a degree of general immunity to the malady is attained. By exposure is meant an equal opportunity to acquire the disease with others who succumb. The individual so exposed either already possesses sufficient special body forces inherited from some ancestor who suffered for him to entirely prevent infection, or, after a more or less prolonged illness develops the required weapons, destroys the invader and ever permanently retains some of his new power, even transmitting it to his descendants.

So it has been with the Jews, whose present representatives are reaping a reward for the long-suffering from their ancestors and who now enjoy a greater general vitality than any other, at least under the conditions of the modern world.

EXOPHTHALMIC GOITER.*

By AUGUSTUS A. ESHNER, M.D.,

PHILADELPHIA.

Long considered a blood-dyscrasia or a circulatory disorder or an affection of the nervous system, the complex of symptoms known as exophthalmic goiter has in recent times been attributed to excessive functional activity on the part of the thyroid gland, resulting in varied derangements in function through the agency of a supposititious internal secretion. In support of this view is the hypertrophy of the thyroid gland found upon surgical removal or after death, the development of symptoms of the disease or their intensification on administration of preparations of the thyroid gland to healthy persons or to individuals suffering from exophthalmic goiter respectively and the subsidence of the symptoms following ablation or atrophy of the gland. What excites the hyperplasia and the overaction is up to the present time undetermined,

*Read before the Southeast Branch of the Philadelphia County Medical Society, May 17, 1912.

and it may ever remain so. Our knowledge of internal secretions is as yet but fragmentary and incomplete and the physiologist, in conjunction with the internist and the clinical surgeon, has here a fertile field for observation and experiment.

Exophthalmic goiter is a disease of adult life, the average age at which it occurs being between thirty and thirty-five years, although childhood and youth, as well as old age, do not altogether escape. The affection is four or five times more common in females than in males. At times it appears to be superinduced by physical stress or mental strain. In some instances an hereditary or familial tendency to the disease is observed.

The onset of exophthalmic goiter is usually insidious and its evolution gradual. Occasionally it develops abruptly and at times it pursues a fulminant course, terminating fatally within a period of a few weeks. Generally it lasts for months or even years, with remissions and exacerbations. It is an open question in my own mind whether perfect recovery ever takes place. The prognosis is least favorable in cases occurring in early life. The disease may pass over into myxedema from secondary exhaustion or atrophy of the thyroid gland.

While the more obtrusive phenomena of exophthalmic goiter, namely the enlargement of the thyroid gland and the protrusion of the eyes are those generally that first attract attention, careful investigation will commonly disclose that the patient has for some time been irritable, tremulous, restless, perhaps conscious of palpitation of the heart and oppression in breathing, especially on exertion or emotional disturbance, of a sense of flushing or of heat, with or without increased perspiration. As most of the sufferers are women and as some of the phenomena mentioned occur in conjunction with the menstrual function and with pregnancy, their significance may for a time escape recognition. Moreover, transitory fullness of the thyroid gland sometimes occurs under the same conditions, while menstrual derangements are not uncommon in the course of exophthalmic goiter. Difficulty in breathing and in swallowing and choking sensations, with a feeling of constriction of the throat, perhaps with actual increase in the size of the neck, will eventually attract attention to the enlargement of the thyroid gland, in which one lobe or both lobes and even also the isthmus may take part. At the same time, or possibly earlier, or soon afterward, the eyes present their characteristic staring appearance, with retraction of the lids, infrequency of winking and protrusion and restricted mobility of the globes. These changes also may be symmetrical or they may preponderate on one side. On examination, the pulse will be found rapid, sometimes in an extreme degree, the heart overacting and perhaps arrhythmic, and a characteristic, roaring bruit often is audible over the full, soft, and sometimes pulsating thyroid gland, while the blood-pressure is subnormal. Cardiac murmurs are not necessarily present. Dermographism is demonstrable. The patient presents an agitated appearance, with fine tremor of the fingers and of other parts of the body, while the face is likely to be flushed and the skin moist. There is complaint of a sense of weakness and sleep often is disturbed. The bowels may be loose, the stools containing an excess of mucus or membrane, and the urine may contain sugar and at times albumin. Changes in the skin, pigmentary and otherwise, have been noted in some cases and profound mental disturbances in others. Hemorrhages may take place from various mucous surfaces or into the skin.

The treatment of exophthalmic goiter has been most varied, partly in accordance with the prevailing conception of its pathology, partly on an empirical basis. It comprises the use of drugs, such as arsenic and iron, digitalis and strophanthus, aconite and veratrum viride, quinine and strychnine, ergot, belladonna, nitroglycerin; the administration of preparations of the thymus and even of the thyroid gland; the blood serum and milk of thyroidectomized animals; the serum of animals treated with hypertrophied thyroid gland; the application of electricity in its various modalities; the employment of the rest-treatment, and finally surgical procedures, such as resection of the cervical sympathetic, cutting off of the arterial supply of the thyroid gland, and partial ablation of the gland itself. Preparations or derivatives of the adrenal gland or of the posterior portion of the hypophysis might be expected to act as physiological antagonists to the excessive thyroid secretion, but, unfortunately, they appear to be wanting in therapeutic efficacy in the case of exophthalmic goiter. In my own experience I have seen the best results from the employment of strophanthus, with or without sedatives, such as bromides, and with rest treatment, and, these failing, from resection of the thyroid gland.

1019 Spruce Street.

A CASE OF HENOCH'S PURPURA TREATED WITH HUMAN BLOOD SERUM; RECOVERY.*†

By S. J. WILSON, M.D.,

BROOKLYN, N. Y.

HOUSE PHYSICIAN, JEWISH HOSPITAL.

The successful therapeutic application of blood serum in the treatment of hemorrhages from various causes has been reported by many investigators in the recent literature. Thus Weil treated eleven cases and Wirth twenty cases of hemorrhage in this manner with gratifying results. To these may be added the following case of Henoch's purpura:

X., a boy, nine years old, born in the United States, and attending school, was admitted to the hospital February 2, 1912. Family history: Parents are living and well. No history of rheumatism or hemophilia on maternal or paternal sides. Previous history: Had measles, mumps, and diphtheria without complications. Has had three or four attacks of tonsilitis during the winter months of the last two years. Has had a few very mild attacks of epistaxis, preceded by a slight headache, the epistaxis stopping promptly and spontaneously. Present illness: Three days before admission to the hospital he began to complain of pain in his legs. His mother subsequently noticed a red eruption over the tibia. The following day he complained of abdominal pain and an ice bag was applied to the abdomen. On the day before he was admitted to the hospital an eruption of the same character as the one on the tibia was noticed on the abdomen, where the ice bag had been applied. He also vomited several times, the vomitus containing food remnants and some blood. During these three days he had fever and passed less urine than usually.

Physical examination: The patient is well devel-

*Read at a meeting of the Williamsburg Medical Society, March 11, 1912.

†From the medical service of Dr. Leon Louria at the Jewish Hospital of Brooklyn.

oped, but anemic. He is drowsy and answers questions correctly, though very slowly. He tosses from side to side and seems to be quite exhausted, with occasional sighing respiration. Neck: Tenderness on pressure over the suboccipital region and cervical vertebræ. Very foul odor from the mouth, and teeth are in a bad condition. Tonsils are enlarged, but not inflamed, and in the center of each tonsil there is a grayish, punched out, ulcerated area with ragged edges and angry-looking base. Edges are slightly inflamed. Glands are not enlarged. Chest: No irregularities. Lungs: Negative. Heart: Regular in rhythm and force. No murmurs heard. Pulse rapid, 120 per minute, of a very small volume, and easily compressible. Abdomen: No distention. Slight tenderness on palpation over the whole abdomen. Liver not palpable. Spleen, lower border palpable, not tender. Skin: A large ecchymotic spot over the upper end of each auricle. Over both cheeks and over the chin there are several discrete ecchymotic spots, slightly raised above the level of the skin, and somewhat indurated. These are all tender. Some are yellow while others are of a red or dark red color. Over the dorsal surface of the left arm, around the elbow and the left index finger, and also over the inner side of the right elbow are seen similar areas. Hemorrhagic spots of varying sizes and shapes are also seen over the spine of the left scapula, over the inner aspect of both thighs, and over the anterior aspect of both tibiæ. Over the abdomen, in the umbilical region, the skin has a purplish discoloration, with many bright red spots in it. This is the area to which the ice bag has been applied. The hemorrhagic spots do not disappear on pressure and are not raised above the skin. In some places these spots are discrete, while in others they are confluent. There are also two large purplish areas which are slightly raised over the inner malleoli. Urine: 1012, acid, heavy trace of albumin and a few leucocytes. Blood: Red blood cells, 4,500,000; hemoglobin, 70 per cent.; leucocytes, 19,600, with 80 per cent. polymorphonuclears. Coagulation time, 5 to 6½ minutes. Throat culture: Predominating organisms, *Streptococcus longus* and *Staphylococcus citreus*. Temperature: 100.8°; pulse, 120; respirations, 28. Clinical history: On the day of admission the patient vomited a greenish fluid containing no blood. The patient received 2,000 units of diphtheria antitoxin and in the evening was more restless, the sighing respirations having markedly increased. The first day after admission the patient was very drowsy. His peripheral circulation was very poor. His lips were cyanotic and had a few dark blue blotches. A few new rose-colored spots appeared over the sacrum. Marked tenderness was observed about the knee and ankle joints, where subcutaneous bluish discolorations could be seen. Pain on motion in these joints was marked and there was evidence of effusion in the left knee joint. The patient vomited a green fluid with bright red blood in it. Temperature was 102°, pulse was very small and rapid, and the extremities were cold. No change in the former skin eruptions or in the ecchymotic areas. The patient's condition believed to be hopeless. The following day his condition was not improved and serum therapy was decided upon. Venesection was performed on the father and fifteen ounces of blood were obtained. The edges of the two angry-looking areas over the tonsils became smoother, but the base was still necrotic. Slight cervical glandular enlargements were present. Heart: A faint systolic murmur was heard over the apex and was not transmitted. New deep rose-colored spots, irregular in outline and of different sizes, ranging from that of a pinhead to the size of a twenty-five-cent piece, were present over the fore and upper and outer parts of the thighs and over the sacrum. These spots were not raised above the skin. Over the inner aspect of the knees and ankles, where the bluish discolorations were previously visible, there are now seen bright, red, large, irregular blotches. These were raised in some places and had a darker hue in the center. The patient again vomited eight ounces of greenish fluid, with no blood in it. He was alternately delirious and drowsy. The first injection of 45 cubic centimeters of serum obtained from the father's blood was given subcutaneously. Blood culture: Sterile. The feces contained blood, which was evident macroscopically as well as microscopically. On the third day after admission the hemorrhagic spots over the forearms were slightly raised. Over the knees and ankles the red blotches seemed to have become smaller, fading at the periphery and becoming darker and scaly in the center. The gums were bleeding, and the two spots over the tonsils were now of a brownish red color and had regular edges. A new small ulceration was seen on the inner aspect of the right cheek, while on the inner aspect of the left cheek an ulceration with a grayish base about the size of a dime was noted. The elbows, wrists, knees, and ankles were painful on motion, but an effusion was manifest only at the left knee. A second injection of 45 cubic centimeters of father's serum was given subcutaneously. Pulse, 150. The patient vomited six ounces of brown fluid containing blood. On the fourth day after admission the pulse had fallen to 120 and the patient felt chilly at times. The extremities were warm and there was no cyanosis of the finger or toe nails. Heart: Systolic murmur at apex, very distinct but not transmitted. The patient did not vomit and was more comfortable. The hemorrhagic spots and blotches were no longer raised and seemed to be fading. A third injection of 72 cubic centimeters of serum from the father's blood was given subcutaneously.

On the fifth day after admission the purplish spots over the abdomen were disappearing, and the other eruptive areas were fading. There were no new eruptions over upper extremities, but a few new hemorrhagic spots were noted over the anterior aspect of the knees. The two areas over the tonsils looked healthy, appearing as two small punched-out depressions. The ulcerated area over inner aspect of left cheek did not improve. Feces did not contain blood macroscopically, but gave a positive benzidin test. The spleen was palpable. On the sixth day after admission a second venesection was performed on the father and about twelve ounces of blood were obtained. On this day the patient vomited a clear blood-colored fluid containing no clots. The left knee was still very tender and swollen, the patella was floating, and the lateral spaces were bulging, the circumference of the knee being 29 centimeters, while that of the right knee was only 27 centimeteres. The hemorrhagic spots all over the body had small pinhead-sized bloody scabs in the center and a faint red margin. The large red blotches were scaling. No new eruptions appeared, the temperature was declining, and the pulse was 104, the lowest rate since admission. A fourth injection of 90 cubic centi-

meters of serum from father's blood was given subcutaneously. On the same day the eye grounds were examined by Dr. Beery, who reported as follows: Left fundus: Many small fresh retinal hemorrhages. Right fundus: A few fresh hemorrhages. On the seventh day after admission the patient was comfortable. There were no sighing respirations. The hemorrhagic spots were fading and scaling. Joint tenderness was still present. The ulcer on the inner aspect of the cheek was deeper and had undermined, irregular edges. A fifth injection of 90 cubic centimeters of father's serum was given subcutaneously. On the eighth day after admission cultures from the ulcer of the cheek showed many staphylococci and some bacilli. On the tenth day after admission the temperature had been normal for the past two days, and pulse ranged from 84 to 106. The patient was comfortable and very lively. The joint tenderness had all disappeared. The left knee still measured 28.5 centimeters, and the patella was floating, but motion was not so painful. Feces were negative as to blood, even with the benzidin reaction. The eruptions were fading rapidly. The dark, bloody scab over the auricles and over the outer side of knees and elbows were still present, but drying up. The spleen was still palpable. A faint systolic murmur was present at the apex, but was not transmitted. The ulcers over inner aspect of cheeks were rapidly healing up.

On the fifteenth day after admission there were no elevation of temperature and no new eruptions, and the color of the old eruptions was becoming yellow and pale pink. Feces: Negative as to blood. Eyes: No fresh hemorrhages, though the outlines of the old hemorrhages were still present. Spleen: Barely palpable. Effusion of left knee gone and circumference now measured 27 centimeters, same as the right. On the nineteenth day after admission the spleen was not palpable. The heart murmur was very faint and was heard only on exertion. Blood count showed 3,100,000 red blood cells, 50 per cent. hemoglobin, 5,200 white blood cells, with 69 per cent. polymorphonuclears. From now on the patient was gradually placed on a regular diet and was allowed to walk about. He gained in weight and strength rapidly. He was discharged March 9, 1912, in perfect health, with the following blood count: Red blood cells, 4,800,000; hemoglobin, 75 per cent.; white blood cells, 8,800, with 60 per cent. polymorphonuclears. As the accompanying chart shows, the pulse came down 48 hours after the injection, while the temperature began to come down 72 hours after the same injection. The temperature and the pulse were highest on the day that the largest number of hemorrhages occurred.

Before considering the efficacy of the serum in this case we must endeavor to explain the etiology of this condition. The two ulcerated ragged areas on the tonsils at the onset of the disease, and later the two angry-looking ulcers on the inner aspect of the cheeks led us to believe that the condition was due to toxins in the circulation absorbed from these ulcerated areas. The damage by the toxins was done, not to the blood, but to the wall of the blood vessel, for the coagulation time was not altered. These toxins Flexner calls endothelialysins, and their action can be explained, according to the Ehrlich side chain theory, as follows: The endothelial cells of the walls of the capillaries have normally a certain protecting substance that does not allow their disintegration and the escape of blood between them. The toxins unite with this substance, and thus disintegration of the endothelial cells and escape of blood takes place. The fresh human serum injected supplies a hyperabundance of this protecting substance and the bleeding stops, so that the disintegration of the endothelial cells and the extravasation of blood ceases. The serum can be administered in three different ways: Intravenously, subcutaneously, or locally. The subcutaneous is the most convenient and is given in the same manner as diphtheria antitoxin. The local method can be used in conjunction with either of the other two methods by applying to the bleeding point gauze soaked in the serum. The subcutaneous dose advised by many is from 20 to 40 cubic centimeters each day, but 45 to 90 cubic centimeters can be given daily. By the intravenous method the dose should be smaller, about 20 cubic centimeters at a time. It is best to use the serum from the blood of a near relative, but any human serum is satisfactory, and even horse serum may give an almost identical result. Venesection is employed for obtaining the serum, which can be used even when it is fourteen to sixteen days old. Direct transfusion will at once suggest itself to many as a better and more efficient method of treatment, but the operation for transfusion itself and the danger of infecting the donor in cases where the purpura is due to an infecting organism, make this method inconvenient and dangerous.

I desire to express my thanks to Drs. Leon Louria and William Lintz for suggesting this method of treatment, and for assisting me in preparing the report of this case.

Surgery of Cancer of the Cardia.—A. Parcelier points out the feasibility of radical intervention in cancer confined to the cardiac end of the stomach. It appears to have been well established that such tumors cannot be extirpated solely by the abdominal route. The abdominothoracic route, such as has been described by Janeway and Green, is the best, although for exploratory purposes alone laparotomy is sufficient. The thoracic stage in the operation must be conducted under differential pressure or with the aid of tracheal insufflation anesthesia. The latter procedure enables one to secure immobility of the lung, which facilitates the various manipulations. An important point in this operation is that of drainage. The line of sutures closing up the opening in the stomach should be within the abdominal cavity. The diaphragmatic wound should be closed and the esophagus carefully fixed to the diaphragm. Drainage should be effected through the peritoneal cavity.—*Archives Provinciales de Chirurgie.*

Alopecia Universalis with Dystrophy of the Nails.—J. H. Sequeira reports the case of a sturdy boy, aged 4, whose mother stated that he was born with the usual amount of hair, but that when he was six weeks old the hair of the scalp, eyebrows, and the eyelashes came out, and since then the boy had been completely bald. Both parents were in good health and there was no history or evidence of syphilis. There were two other children; one has had rheumatism and the other has been quite healthy. There was no history of any similar affection of the hair and nails in any member of the family. There have been no miscarriages, and the patient was born at full term. The child presented the usual features of complete alopecia. All the nails of both hands and feet were narrow, laterally curved, and elevated from their beds at the distal extremities. Under the free margins there was a brownish-black horny mass. There were no other abnormalities. Thyroideum siccum in tablet form had been given, but, so far, without improvement.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, August 10, 1912.

DIPHTHERIA ENDOTOXIN IN THE TREATMENT OF DIPHTHERIA INFECTION.

THE success attending the employment of antitoxin in the treatment of diphtheria has apparently diverted attention from any other factor in the pathogenesis of this disease than the soluble toxins of the diphtheria bacillus. The possible rôle of the insoluble toxins of this microorganism has been barely suspected. On July 11, 1903, E. Rist reported before the Société de Biologie that the bodies of the diphtheria bacilli, freed from their soluble toxins, still possess toxic properties. By inoculating guinea-pigs intraperitoneally with diphtheria vaccines, thus utilizing the endotoxins of the Klebs-Loeffler bacillus, he was able to produce paralysis similar to the clinical forms. These experiments apparently explained why the early administration of diphtheria antitoxin had little or no effect in preventing subsequent paralyses, for, according to Rist, these are the result of the action of the endotoxins upon the nerve cells, the soluble toxins alone being neutralized by the diphtheria antitoxin.

These investigations in spite of their far-reaching importance attracted very little attention. No efforts were made either to confirm or to disprove the pathogenic significance of the insoluble toxins of the diphtheria bacillus. A most promising avenue of research was opened up; nevertheless, no one sought to determine whether it might not be possible to produce an active or passive immunity by means of inoculations with diphtheria endotoxins. From another direction, however, this subject has lately been approached. In an effort to cause the disappearance of diphtheria bacilli from the throats of diphtheria carriers or of chronic cases of diphtheria, the thought suggested itself to R. T. Hewlett and A. T. Nankivell (*Lancet*, July 20, 1912) of inoculating these individuals with the endotoxin of the diphtheria bacillus. The endotoxin was prepared by growing the virulent organism on serum or blood-agar in Roux bottles, collecting the growth, washing it two or three times in sterile physiological salt solution by centrifuging so as to remove any adherent toxin, grinding the bacterial mass by the Macfadyen method in the presence of intense cold, and filtration of the ground mass through a Berkefeld filter. The filtrate contains the endotoxin and is standardized by the addition of sterile salt solution so as to contain two to five milligrams of the endotoxin per cubic centimeter. It was found by Hewlett that the endotoxin is harmless to guinea pigs and that to a considerable extent it protected these animals against injections of living diphtheria bacilli.

It is pointed out that ordinary cases of faucial diphtheria are not, as a rule, free from infection for four or five weeks after the onset of the attack. In addition to receiving the usual injection of antitoxin, five individuals suffering from tonsillar diphtheria of moderate severity were inoculated on the following day with 2 milligrams of the endotoxin. In four of these cases the diphtheria bacilli disappeared from the throat within two weeks after the inoculation with endotoxin. In another series of cases the patients had harbored diphtheria bacilli for many weeks or months. As the result of one or more injections with the endotoxin, all of the cases showed definite improvement, the diphtheria bacilli either disappearing entirely or greatly diminishing in numbers.

The treatment of the diphtheria carrier is an important problem in preventive medicine. The use of antiseptic sprays and gargles, and even of sprays of living microorganisms, such as the *Staphylococcus aureus*, may serve to reach the diphtheria bacilli exposed on the surface of the fauces, but are not effective in reaching the organisms hidden in the crypts of the tonsils or in the accessory sinuses of the nose. The endotoxin method, which may be compared with the vaccine treatment of other persistent infections, apparently serves to combat these hidden foci better than any other measure yet proposed. It has been found that the best results followed an initial dose of 2 milligrams of the endotoxin; if necessary, a dose of 5 milligrams is given a week or ten days later, and even repeated after a similar interval if the culture from the throat is still positive.

ARTIFICIAL VERSUS NATURAL SELECTION.

EUGENICS is very much to the front in these days. There are those, especially in Great Britain, who claim that the salvation of the civilized races hinges on the practical recognition of the laws of heredity. Many great authorities state that in all industrial countries degeneracy is on the increase. Of all countries Great Britain is the most industrial and therefore it is there that degeneracy is most marked. Up to the present time industry on a large scale has meant the crowding together of masses of people in inadequate areas. Of the population of Great Britain nearly three-quarters are herded together in cities, and this under existing conditions involves the dwarfing of the people physically and to some extent mentally. The trend of all modern nations is toward commercialism and thus it would appear toward degeneracy. Even in this far stretching land the population is surely drifting in the direction of the cities. The problem then is successfully to combat the forces leading to the production of an inferior stock and the eugenists affirm that this can be effectively done only by artificial selection.

Not all, however, of those competent to speak are unreservedly on the side of eugenics. I. Harris, writing in the *Liverpool Medico-Chirurgical Journal,* proclaims himself an opponent of artificial selection and explains his attitude. In his opinion, eugenics is a "quack remedy" recommended as an infallible cure for the rapid degeneration of the European races. He points out that animal and human breeding are very different matters. In the artificial selection of animals a given quality for a given purpose is sought. What then is the standard that shall guide the followers of Mendel in human artificial selection? Shall physical strength or the purely mental attributes be the criterions of human excellence? Darwinism, or natural selection, effects that the one organism in possession of a superior faculty in its struggle for existence shall survive. Artificial selection, on the other hand, presupposes *a priori* and quite gratuitously the desirability of a certain faculty which it attempts to perpetuate. In Darwinism variability is the main factor in progress. Thus artificial selection can concern itself only with the intensification of a specific faculty, but evolution means progress in manifold directions. It should also be carefully noted that genius often makes its appearance as an abnormality difficult to distinguish from the degenate, such as the eugenist would reject. The families of the genius and the great are frequently tainted by insanity, cancer, gout, and tuberculosis, but would the world have been the better without them? Variety is the spice of life, and this axiom applies to the breeding of men and women. We do not want, Harris says, a race of magnificent animals of a like type. It is not, he contends, artificial selection which is needed, but a cessation of the methods now being taken to preserve the unfit. Left to themselves, the unfit will disappear without the aid of eugenics. At any rate, it may be confidently stated that enough is not yet known concerning the working of the principles of eugenics to warrant the optimistic assertions of its too enthusiastic followers. The cold searchlight of reason must be turned on the matter for some time to come ere the teachings of Mendel can be put into practice so far as the human race is concerned; all of which does not mean that society should permit criminals and degenerates to propagate and perpetuate their kind without heed or restraint.

FACTORS OF SAFETY.

After the recent Harvard-Yale boat races it was the three losing crews which evidenced the greatest exhaustion; in one instance the men were so "all in" that they had to be lifted from their boat. One might have expected the reverse—that the victors, having taken the extra exertion necessary to win, had worked more nearly to the limit of their powers and had been more used up in consequence. But this would not be taking into account the stimulus of victory on the one hand, and the depressing effects of defeat on the other. Spitzka has estimated that the mortality from wounds in a defeated army is in proportion to that of the victors as four to three or even as three to two. The explanation of such phenomena must be that success reacts upon and brings into greater play one's factors of safety, while failure has the reverse effect to depress these factors. The term was borrowed from the mechanical engineer by S. J. Meltzer when he addressed the Harvey Society on "The Factors of Safety in the Animal Structure and the Animal Economy."

These factors are the body's reserve forces, which avail in times of undue stress and strain; they keep the living organism in fairly normal condition despite many untoward environmental agencies. By the term "factor of safety" the mechanical engineer designates the margin of safety required in constructing engines, bridges, houses, and the like. If, for instance, the tensile strength of boiler steel plates and stay bolts is 60,000 pounds to the square inch, the actual stress which is allowed for the work of the boiler should not be more than 10,000 pounds per square inch for the plate and not more than 6,000 pounds per square inch for the stay bolts—which means that the stress to which the plates may be exposed in the boiler should be only one-sixth or one-tenth the actual strength of the steel. The factors of safety here are six for the plate and ten for the bolts. Thus mechanical structures are expected to withstand not only the stresses of reasonably expected maximum loads, but also those of six or seven times such loads.

The factor of safety is founded upon finite human ignorance of what might happen, and a commendable desire to provide against such contingencies. The human machine is of complexity quite infinite; and it is much more difficult to foretell the possible strain, the stress of environment, accidents, the attacks of pathogenic organisms, and the myriad other agencies hurtful to the human machine, many of which we are powerless to prevent, concerning many of which we are in ignorance—ignorance, however, which modern medicine is more and more dissipating.

In the human machine the potential energy in many organs—the heart, the liver, the kidneys—far exceeds the needs of normal, every-day existence. In the case of many functions the necessary mechanisms are doubled and even trebled. One organ is often assisted as to its functions by other organs. And living tissue is provided with one factor of safety that is peculiar to sentient existence and which does not obtain with any other kind of existence—the mechanism of self-repair.

Thus do factors of safety provide the integrity of life and the perpetuation of the species; and they have an important bearing on the process of natural selection. Thus becomes comprehensible the saying, "The half of his strength he put not forth"; for every man has in him a latent potentiality. Factors of safety explain also how under stress of fright or under the inspiration of great affection or other tremendous emotion, things have been accomplished of which the doer would never have believed himself capable. And to medical science is it especially known that many men and women complete the span allotted them, despite the many diseases, accidents, and other untoward circumstances to which human life is constantly sub-

ject. And in arousing a patient's latent capabilities the physician will oftentimes make wise suggestion an adjuvant to cure.

Infection Following Tonsillotomy.

It has been recognized for a long time that the tonsils may serve as a portal of entry by which many types of pathogenic microorganisms gain access to the circulation. Little attention, however, has been paid to the dangers of serious infection that may occur through the wound left after removal of the tonsils, whether by tonsillotomy or by enucleation of the tonsils. H. Koplik in the *American Journal of the Medical Sciences*, July, 1912, calls attention to this possibility, and in addition to a few instances that he has observed, cites a number of cases that have been reported in the literature. He refers to three forms of infection that may follow removal of the tonsils, or of adenoids, or of both structures: (1) Following the operation the patient may appear to be doing well, but on the second or third day the temperature begins to rise and continues to run an obscure course for about two weeks. The patient recovers without any ill effects on the heart, and with no rheumatic manifestation. (2) In another set of cases, following the removal of the tonsils, there occurs a moderate rise of temperature which may continue for a number of weeks. In the meantime cardiac murmurs appear, and the patient may even succumb to a malignant form of septic endocarditis. (3) In the third class of cases the infection is a severe one, and causes destructive blood changes with such evidences of sepsis as the presence of ecchymotic and petechial areas on the skin, and of patches of bronchopneumonia, together with the occurrence of profuse hemorrhages from the bowel. An interesting case of this type is reported by the author. It was one of profound sepsis in a boy aged five years following the operation of tonsillectomy and adenectomy performed amid the ideal hygienic surroundings of an institution. There occurred seven hemorrhages into the skin and conjunctive and from the mucous membranes. This hemorrhagic form of sepsis was also accompanied by a rise of temperature and the development of an endocarditis. Transfusion was performed as a last resort and succeeded in saving the life of the patient.

A New Method of Applying Carbon Dioxide Snow.

Carbon dioxide snow as a cauterizing agent has in many respects revolutionized the treatment of various skin affections. The application of this agent is distinguished by its simplicity as well as by its excellent cosmetic effects, a valuable desideratum when disfiguring scars on the face or on other exposed parts of the body are concerned. W. Knowsley Sibley writes in the *Practitioner* for July, 1912, concerning a new method of applying this remedy. He has found that carbon dioxide in solid form will mix with and form a solution in ether or in absolute alcohol. This mixture is what may be considered for all therapeutic purposes a preparation of liquid air, but without its unstable character and dangerously low temperature. It can be easily painted on the skin as a stimulating or cauterizing agent, according to the length of time the reagent is applied. However, only more or less superficial lesions can be dealt with by this method, as it is not possible to exert any great amount of pressure, the degree of which is so important in treating deeply seated lesions with solid carbon dioxide. Still, if a deeper action be required a well compressed lump of solid carbon dioxide may be soaked in ether or absolute alcohol and then applied by a pair of forceps to the skin. According to Sibley, in the treatment of superficial conditions the solution of carbon dioxide in ether is superior by far to the methods formerly adopted because the part under treatment is exposed to view the whole time, and the area dealt with, however irregular in outline, can be so easily defined. Especially is the method satisfactory for application to small or large patches of lupus vulgaris.

Pathological Portraits.

Diagnosis of unsuspected disease in a person long dead through portraits is no new thing, but on account of the rapid progress of medical knowledge each generation may read new meanings into an old likeness. There is no doubt that much of the fanciful is present in these diagnoses. It has been stated seriously that Beethoven had the facial configuration of a heredosyphilitic, and this possibility has been invoked to explain his deafness and other individualities. Poe's portrait has been asserted to show evidences of hydrocephalus, despite the fact that the survival of sufferers from this affection beyond twenty years or so has been pronounced impossible. Naturally Poe's well-marked degeneracy is readily explained on the basis of such a defect. At a recent meeting of the K. K. Gesellschaft der Aerzte of Vienna (*Münchener medizinische Wochenschrift*, June 25) Kronfeld discussed the pathological portrait and bust. He states that these are extremely numerous, but considers the subject in broad lines only, referring the reader to standard works like those of Hollander. Artists have of course often been called upon to paint those actually deformed, ill, or disabled—blind people for example. With this sort of pathological portraiture we have no concern. The representation of affections which no longer exist among us would of course possess high value, but few such are known to exist. The absence of teeth, including false dentures, is an example of this sort which would hardly be possible to-day in the class of people who have portraits painted. One of the commonest pathological portraits is the adenoid facies, the nature of which must have been quite unsurmised. It is possible that women apparently gravid who sometimes appear in portraits without any apparent reason were painted from models having enteroptosis. Style and fashion among painters cannot be omitted from consideration in this connection, as Botticelli, Dürer, and others are said to have had a tendency to paint their women with peculiar configuration of the abdomen.

News of the Week.

Fighting the Plague.—Assistant Director Edward Francis of the Government Hygienic Laboratory left Washington for New Orleans on August 3, ordered there to assist the local authorities in warding off the invasion of plague. Dr. J. F. Harrison of Mobile has been appointed temporarily a member of the Public Health and Marine Hospital Service to inspect vessels entering the port of Mobile, and direct their fumigation. No new cases

of the plague were reported in Havana or in Porto Rico during the week ending August 3rd. A case of the disease was discovered in Liverpool on Monday of this week.

Yellow Fever in Panama.—The occurrence of a single case of yellow fever has caused the establishment of a quarantine against Panama by Costa Rica, a detention of four days being required. This is the first time that a quarantine has been established against the Isthmus in nine years.

Typhoid Fever in Porto Rico.—An epidemic of typhoid fever prevails in the municipality of Penuelas, eight miles from Ponce, in Porto Rico. In a population of about twelve hundred, there have been seventy cases of the disease, with five deaths in three weeks. The infection has been traced to the water supply, which is received from the river, and arrangements have been made by the Director of Public Health to have water from another source brought into the town.

Health of Cuba.—The Cuban Cabinet on August 3 adopted a resolution declaring that Cuba would welcome an American commission for the investigation of Cuba's sanitary condition, and also declaring that Cuba would be found in the matter of health to compare favorably with any country in the world.

Cleaning-Up Week.—Charity organizations, the Department of Health and the Department of Street Cleaning of New York, assisted by the Boy Scouts, began on July 29 a "clean-up" week in New York.

Ambulance Surgeon Hurt.—Dr. Charles Frazer, interne at the Williamsburg Hospital, was seriously injured on July 31 when the ambulance in his charge was struck by a trolley car and overthrown. Both the surgeon and the driver were thrown out, the surgeon sustaining a fractured skull and internal injuries.

Caring for Babies.—The Commissioner of Health of New York reports that during the week ending July 27, there were in the city 349 deaths of babies under one year of age, or 26 less than during the corresponding week a year ago. This makes a total decrease in infant deaths so far this year as compared to last of 456 in the entire city. The saving has been in Manhattan Borough, where the deaths have decreased by 508, and in Queens, where the decrease is 41. In the other boroughs there have been slight increase in the number of deaths; in the Bronx 41; in the Borough of Brooklyn, 33; and in Richmond, 19. It is estimated that about 43,000 babies are under the care of public and private agencies this summer.

Gifts to Charities.—The New York Polyclinic Medical School and Hospital receives a bequest of $3,000, and the White Plains (New York) Hospital Association one of $500, by the will of the late David J. Garth, of East Chester, New York.

By the will of the late Simon Adler, of New York, the sum of $500 each is left to the Lebanon and Beth Israel Hospitals of that city.

Dr. J. Anna Norris, of Chicago, has been appointed director of health and physical training for women at the University of Minnesota.

A Bill to Amend the Pure Food and Drug Law.—The Interstate Commerce Committee has favorably reported the bill of Representative Shirley to amend the pure food and drug act. This measure prohibits "false and fraudulent" curative claims on labels. It seeks to meet a decision of the Supreme Court that the putting forth of false and extravagant claims regarding the curative powers of medicines was not in violation of the pure food law.

VI. International Congress Midwifery and Gynecology.—Under the patronage of the Empress of Germany, this congress will meet at Berlin on September 9 to 13, 1912. The president of the congress is Geh. Med.-Rat. Prof. Dr. E. Bumm, and the secretary-general Privatdozent Dr. Ed. Martin, who may be reached at Berlin N. 24, Artillerie St. 18.

Obituary Notes.—Dr. John Jay Taylor, of Philadelphia, died on August 1 at his summer home in Ocean City, N. J., after a protracted illness. Dr. Taylor was born in 1853 and was graduated from the Medico-Chirurgical College, Phialdelphia, in 1887. He was editor of the *Medical Council* and formerly one of the editors of the *Medical World*, his entire medical life having been devoted to literary work. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania and the American Medical Association, and of the American Medical Editors' Association.

Dr. Joseph E. V. Mathieu of Central Falls, R. I., a graduate of the Medical Department of Victoria University, Toronto, in 1879, coroner of Central Falls for ten years, and for the past three years State Senator, died at his home suddenly of heart disease, on July 12, aged 49 years.

Dr. Russell Caffery of San Antonio, Tex., a graduate of the Medical Department of the Tulane University of Louisiana in 1891, and a member of the American Medical Association and the Texas State, Bexar County, and West Texas Medical Societies, died at his home of uremia, after a short illness, on July 11, aged 44 years.

Dr. John Kurtz, formerly of Moorhead, N. D., and a pioneer physician of the Red River Valley, a graduate of the George Washington University, Department of Medicine, Washington, in 1870, died at his home in Washington, D. C., on June 30.

Dr. Frederick C. Boyd of Kingston, Ontario, a graduate of Queen's University Medical Faculty, Kingston, in 1911, and for a short time interne at Columbus Hospital, New York, died at his home of tuberculosis, on July 5, aged 23 years.

Dr. Alfred M. Haight of White Plains, N. Y., a graduate of the New York Homeopathic Medical College and Hospital in 1879, a member of the American Institute of Homeopathy, the Academy of Pathological Science, and the New York State and Westchester County Homeopathic Medical Societies, and attending physician to the White Plains Hospital and the Jennie Clarkson Orphans' Home, died suddenly of heart disease at Ocean Grove, N. J., on July 14, aged 57 years.

Dr. W. R. Trotter of Fort Des Moines, Iowa, a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1882, died at his home of paralysis, on June 29, aged 61 years.

Dr. Henry Giles Anthony of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1884, a member of the American Medical Association, the Illinois State and Cook County Medical Societies, the American Dermatological Association, and the Chicago Dermatological Association, assistant professor of skin and venereal diseases in the Rush Medical College, and professor of skin and venereal diseases in the Chicago Polyclinic, died at his home, on July 10, aged 52 years.

Dr. Frank Fife of Dayton, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1892,

formerly assistant superintendent at the Dayton State Hospital, and a member of the Ohio State and Montgomery County Medical Societies, died at his home of uremia, on June 29, aged 47 years.

Dr. William Guy Richards of Tarrytown, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1878, died at his home, on June 30, aged 61 years.

Dr. Henry M. Field of Los Angeles, Cal., a graduate of the College of Physicians and Surgeons, New York, in 1862, formerly professor of therapeutics in the Dartmouth Medical College, Dartmouth, N. H., a member of the Boston Gynecological Society and a non-resident member of the New York Academy of Medicine, died at his home on July 11, aged 73 years.

Dr. Sprague Winchester of Natchez, Miss., a graduate of the medical department of the Tulane University of Louisiana in 1892, died suddenly at his home on July 20, aged 53 years.

Dr. Heneage Gibbes of McAlester, Okla., a graduate of the University of Aberdeen, Scotland, in 1879, died at his home on July 21.

Dr. Theodore F. Watkins of Philadelphia, Pa., a graduate of New York University Medical College in 1861, died at his home on July 23, aged 79 years.

Dr. Robert Fulton Boyd of Nashville, Tenn., a graduate of the Meharry Medical College, Nashville, in 1882, and professor of gynecology and abdominal surgery in his alma mater, died suddenly at his home on July 20, aged 54 years.

Dr. Jesse B. Hyland of Keene, N. H., a graduate of the Harvard Medical School, Boston, in 1884, and a member of the American Medical Association and the New Hampshire State and Cheshire County Medical Societies, died at his home after a brief illness, on July 11, aged 50 years.

Dr. Horace M. Bellows of Huntingdon Valley, Pa., a graduate of the Medical Department of the University of Pennsylvania in 1861, and a surgeon in the United States Army during the Civil War, died in Philadelphia of heart disease, on July 13, aged 73 years.

Dr. Wilbur Fisk Lamont, of Catskill, New York, a graduate of the Albany Medical College in 1889, and a member of the New York State and Greene County Medical Societies, died in the Albany City Hospital in Albany of pernicious anemia, on August 1, aged 49 years.

Dr. John Samuel Bassett, of New York, a graduate of the Berkshire Medical College, Pittsfield, Massachusetts, in 1850, died at his summer home in New Milford, Connecticut, on July 31, aged 84 years.

Dr. John Solomon Kreiter, of Akron, Pennsylvania, a graduate of the Bellevue Hospital Medical College, New York, in 1882, and a member of the Pennsylvania State and Lancaster County Medical Societies, and for many years of the Akron School Board, died at his home on July 18, aged 59 years.

Dr. Van Duyne A. Sutliff, of Philadelphia, Pennsylvania, a graduate of the Medico-Chirurgical College of Philadelphia, in 1902, a member of the Pennsylvania State and Philadelphia County Medical Societies, and demonstrator of anatomy in his alma mater, died at his home on August 1, following an operation for appendicitis, aged 40 years.

Dr. William E. Wood, of St. Louis, Missouri, a graduate of the Eclectic Medical College of Cincinnati, in 1891, and a member of the Missouri State and St. Louis City Medical Societies, died suddenly on July 22, aged 49 years.

Correspondence.

THE PREVENTION OF TETANUS.

To the Editor of the Medical Record:

Sir—The article by Dr. Dowling Benjamin in your issue of June 29 on "The Elimination of Lockjaw," is unquestionably correct, but unfortunately his treatment like that by antitoxin is preventive. What is sought especially is some treatment that is efficacious after tetanus develops. Some of the injuries that result in lockjaw are so small that it is not probable a surgeon will ever be consulted for them.

In a practice of thirty-seven years many cases of tetanus have come under my observation and care, and very insignificant injuries have often been the cause. Since the germ theory of the disease was advanced I have always treated every injury about the hands and feet of children as infected injuries and I have never had a case of tetanus follow any wound so treated. A cut or scratch is easily handled; it is the punctured wound, made usually by a nail through the sole of the foot, that requires care. An injection of some local anesthetic or the inhalation of chloroform or ether is required in the operation for cleaning a wound of this kind. With the patient anesthetized a slit is cut through the skin and tissues at the site of the wound and all foreign particles that may be dragged in by the puncturing body are washed away with an antiseptic solution. This done the wound is wiped to its extremity with a solution of equal parts of tincture of iodine and phenol and then packed with a little moist gauze. In about three days it is freshly dressed with gauze after being washed with an antiseptic. Healing is prompt and without much if any pain, and, like Dr. Benjamin, I feel reasonably certain that this treatment is justified in every case of injury of this nature.

This season I have had two cases of tetanus in children in whom death followed an infection entering through very insignificant cuts on the feet. The cuts were so small that the cases did not come under my care until the muscular spasms had developed. I have used various plans of treatment with poor success in years past. The only cases that have recovered in my practice were treated with morphine hypodermically and hydrate of chloral. But often this treatment has failed. It seems quite certain that if all wounds were properly cleaned and kept clean until healed there would be no tetanus.

Howard Jones, M.D.

Circleville, Ohio.

THE PREVALENCE OF INTESTINAL PARASITES IN THE SOUTH.

To the Editor of The Medical Record:

Sir:—Although articles on some few of the intestinal parasites occurring in the South are beginning to appear in the literature, the question of the prevalence of such parasites has not been touched, except in the case of the hookworm. Recently there was reported an examination of 407 cases in Florida without demonstrating the ameba.* This seems very unusual.

In going over my records of feces examinations in 551 individuals, 521 whites and 30 negroes, 329

*King: Quoted by E. R. Whitmore, *Arch. Int. Med.*, ix, 4, 515-519.

males and 222 females, I find that 370, or 67 per cent., were infested with some of the animal parasites, while 181, or 33 per cent., were uninfested.

The parasites found were as follows, in some instances double, triple, and even quadruple infestations being present:*

Necator americanus	118	
Ascaris lumbricoides	12	
Oxyuris vermicularis	5	
Trichiuris trichiura	1	
Strongyloides intestinalis	12	(2)
Tænia saginata	4	
Hymenolepis nana	27	
Fly larvæ	3	
Amebæ	225	
Lamblia intestinalis	1	(2)
Trichomonas vaginalis	82	

The pathogenic and non-pathogenic amebæ are intentionally listed together, as at present I am uncertain about the occurrence of *Entamœba tetragena* in this locality.

According to age the infestations occurred as follows:

Age.	Cases.	Per Cent.	Positive.	Per Cent.	Negative.	Per Cent.
Under 10 yrs..	70	12.70	55	78.57	15	21.43
10 to 19 yrs..	228	41.38	152	66.66	76	33.33
20 to 29 yrs..	114	20.69	77	67.54	37	32.46
30 to 39 yrs..	68	12.35	40	58.82	28	41.18
40 to 49 yrs..	29	5.27	22	75.51	7	24.49
50 to 59 yrs..	30	5.44	16	53.33	14	46.66
60 to 69 yrs..	9	1.63	5	55.55	4	44.45
70 to 79 yrs..	3	.54	3	100.00	0	0.00
All ages	551		370		181	

The majority of these cases harbored only such harmless commensals as *Entamœba coli* and *Trichomonas vaginalis.*

Hookworm, roundworm, pinworm, and dwarf tapeworm infestations were confined almost entirely to the first two and a half decades of life, while the beef tapeworm, strongyloides, myiasis, and amebæ, both pathogenic and non-pathogenic, seem to occur at any age.

At this time I wish to bring out only one point—that in the South more than one-half of the population, regardless of age, harbor some of the intestinal animal parasites.

William Allan, M.D.

Charlotte, N. C.

*Nomenclature is after Braun. "The Animal Parasites of Man."

THE PREVENTION OF TONSILLAR HEMORRHAGE.

To the Editor of the Medical Record:

Sir:—Some years ago a well known surgeon and a well known throat man could not see things the same way. The surgeon maintained that tonsillar hemorrhage could be stopped by the construction of a well placed ligature, the other man maintained that the requisite ligature could not be well placed and in fact told his students that the placement was impossible. The surgeon told me all about it and I promised to try the method and give him an unbiased opinion of its use in the hands of a green, inexpert, throat man like myself. The very able article in the Medical Record of June 1, 1912, suggests to me that what I did actually do may prove of some value to some one engaged in throat work as I shall probably not have occasion to avail myself of the expedient again—or only in great emergency—as I do not anticipate performing any more tonsillectomies.

I had three cases on which to experiment. In two I cut off the tonsil and then introduced a purse-string suture of No. 1 iodinized catgut as the surgeon suggested. It worked as might be anticipated and the operation was easy. At least it was not to be compared in difficulty with trachelorrhaphy. Then the idea came to me that the ligature should be introduced first and the tonsil cut afterward. If a double threaded needle of the smooth-round variety be passed through the pedicle of a tonsil, which has been pulled out by an army bullet forceps held by an assistant, the direction is a matter of choice. The needle should be pulled clear out of the mouth, a knot tied in the loop which it carried, and then it is a simple matter to pass one free end over the holding forceps, through the loop, to draw all tight into place, to fasten with two or three knots, to cut off the long ends, or to use them as tractors, and to perform a bloodless tonsillectomy. The old-fashioned way of ligating a hemorrhoid gives a good idea of the process.

Linen or silk is the best ligature material and the needle should have no cutting edges. Then if a large artery should be transfixed the probabilities of hemorrhage are decidedly lessened. Manifestly the method would be used solely in such tonsillar conditions as rendered hemorrhage probable. Any one accustomed to the use of a modern needle holder would place such a purse string-pedicle-stitch in a very few minutes and the linen will not soften in moisture, but will cut out in approximately from six to ten days. The fault that I should consider most probable would be too great tension rather than too little. It is somewhat painful and if I intended to employ it I should certainly inject the stump with the novocain-urea solution, the anesthesia from which frequently lasts a week or more.

This letter is purely suggestive and extensive trial might bring out objections which I do not now see.

Douglas H. Stewart, M.D.

128 West Eighty-sixth Street, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL SOCIETY'S 250TH ANNIVERSARY—BICENTENARY OF DUBLIN MEDICAL SCHOOL—TROPICAL MEDICINE APPEAL—INSURANCE AND LIVERPOOL MEETING — NURSES — RED CROSS — CENTRAL HEALTH COMMITTEE FOR LONDON.

London, July 19, 1912.

This week the Royal Society, which we look upon as the chief scientific society in the world and its Fellowship as the blue ribbon among scientific distinctions, has been celebrating the 250th anniversary of its foundation. On Monday there was a somewhat informal reception of the delegates from other countries who came to offer the congratulations of their various institutions. This afforded an opportunity for making the personal acquaintance of the guests and their entertainers. On Tuesday there was a commemorative service in Westminster Abbey in the morning and in the afternon the formal reception of delegates in the society's great library. The addresses brought by these delegates were not publicly read, but each spoke a few words of congratulation to the President and Fellows on this great occasion. The day wound up with a banquet in the Guildhall. On the next two days numerous visits were arranged to places in and around London. There was a garden party given by the Duchess of Sutherland in the afternoon of Wednesday, and in the evening the conversazione of the society was held.

Yesterday the King and Queen gave a reception to the delegates at Windsor Castle. The President

of the Society, Vice-President, Treasurer and Foreign Secretary were presented to their Majesties first, and then the President, Sir A. Geikie, presented the Councillors and the delegates. Afterwards they were invited to join the Royal garden party, to which numerous Indian and Colonial visitors, foreign ambassadors, members of both Houses of Parliament and representatives of the naval and military services, of the musical, dramatic and literary professions and other eminent personages had been invited with their wives and daughters. They formed a brilliant assembly of about 8,000, and their Majesties spent a long time among their guests. The weather was very favorable, not too hot, the "heat-wave" we lately borrowed from you having passed by. To-day a number of the delegates are visiting the universities of Oxford and Cambridge.

An exceptionally interesting memorial of this 250th anniversary has been published. It is a facsimile reproduction of the signatures in the Society's Charter Book, from that of King Charles II, the founder, down to those of the Fellows elected and admitted this year. It consists of two volumes. The names are by no means restricted to science, and from the very beginning of the society every branch of knowledge was freely recognized. Medicine as the chief scientific profession was well represented at the foundation and has maintained its position ever since. Sir Archibald Geikie, the president, contributes to the work an instructive preface explaining the circumstances which led to the formation of the society.

Another very interesting memorial was shown at the conversazione. On the central table was Newton's death mask, a lock of his hair, the manuscript of the *Principia,* the original model of his reflecting telescope, and some other objects. There are places in the manuscript showing another hand correcting it and believed to be Halley's, who cooperated in various ways with Newton and made himself responsible for the cost of printing the *Principia,* for the philosopher at the time was poor as is evidenced by the fact that the society remitted for him the financial dues of the Fellows.

A celebration on similar lines and more closely connected with the profession was held last week in Dublin—the Bicentenary of the Medical School. For three days Trinity College was the scene of academic festivities and delegates from the universities and colleges of numerous countries attended to offer congratulations. The Royal Colleges of Physicians and Surgeons were of course deeply interested and elected Honorary Fellows while the University conferred honorary degrees on distinguished doctors. A meeting of graduates was held under the presidency of Mr. Woods, ex-P.R.C.S.I., when it was determined to establish a permanent memorial of the Bicentenary and a committee was appointed to collect subscriptions and decide on the form of the memorial.

On Wednesday there was a refreshing scene at the Foreign Office—leaders of both political parties met to promote the appeal for the School of Tropical Medicine, Mr. Curtin Chamberlain was in the chair, and among the speakers were three secretaries of State, Sir E. Grey, Lord Crewe, and Mr. Lewis Harcourt. The chairman said that day was selected for meeting as the king had intended to lay the foundation stone of the extension of the School that afternoon on his way to visit the docks but unfortunately that visit had been abandoned. The call on the public by the *Titanic* disaster made it impossible to urge their claim at the same time. Recently some gentlemen had taken the matter up privately. Mr. Otto Beit had promised to add £250 to every £1,000 collected up to £20,000 and he had already paid £4,000 on that account. Mr. Waldorf Astor offered £1,000 if nine others would give the same and the chairman said he was glad to report that a donor who wished to be anonymous had sent him the whole £9,000. Altogether between £17,000 and £18,000 had been collected in the last two or three weeks.

Sir E. Grey said the object was beyond criticism and beyond praise. It had the advantage of being noncontroversial, but things sometimes suffered from that as people thought such claims undeniable. We should be grateful to Mr. Chamberlain for taking up this which owed its inception to his father when Colonial Secretary. The impetus he gave to Tropical Medicine would never be forgotten. Other men, as Sir Patrick Manson, had given expert knowledge and experience. This appeal was not made on a forlorn hope. Enough had been done to show how much was yet to be done and could be done.

Lord Crewe, as one who succeeded Mr. J. Chamberlain at the Colonial office, gave eloquent expression to his interest in noncontroversial matters as well as the combative subjects with which he loved to deal. The chairman would, he was sure, agree with him that the countless admirers of the great statesman could offer no more acceptable a testimonial than a handsome addition to the resources of this School. At the India office as well as that of the colonies they appreciated this great work.

Mr. Lewis Harcourt said he need not repeat what he had been saying for the last six months but would thank Mr. A. Chamberlain for the splendid, untiring energy he had put into this work, but for whose efforts the subscription list would never have reached what it had.

See how "good and pleasant it is for brethren (politicians?) to dwell together in unity!" Parties profess agreement on noncontroversial subjects and on Tropical Medicine they have shown they mean it. Why not on Insurance? The Liverpool meeting is upon us and that is to decide whether to break off negotiations. Yesterday in an interview with the press Mr. Masterman, financial secretary, threatened that if an agreement cannot be come to medical benefit may be suspended. We shall see.

On Monday Queen Alexandra entertained her auxiliary committee of the Queen Victoria Jubilee Nurses Institute for its sixth annual meeting. This committee helps the Jubilee Institute much as the League of Mercy helps the Hospital Fund. Two hundred or more ladies pledge themselves to raise at least £10 each during the year, so securing a sum of £2,000 for the work. The actual sum for 1911 was £2,071—19. On Tuesday Queen Alexandra gave a reception in honor of the British Red Cross Society. Upward of 1,000 members of committees, presidents of branches, and others interested were entertained in the garden of Marlborough House on one of the finest summer days of this year.

A conference of persons interested in promoting the Health of London was held in the Mansion House on Tuesday. Sir M. Beachcroft said the object was to ascertain whether sanitary authorities and voluntary agencies could be brought into closer communication so as to avoid overlapping and waste. Some thought that the work of the two

agencies was too distinct. Others held that in health matters local organizations were best and a new central authority unnecessary. After discussion on the motion of Dr. Allan, seconded by Sir John Tweedie, it was decided to be desirable to establish a "Central Health Committee for London" representing the various agencies at work and to promote joint action between Metropolitan and Municipal authorities and voluntary societies engaged in the prevention of disease and the education of all classes in hygiene. It was further decided to invite the co-operation of a long list of such agencies and to ask the Local Government Board to allow the meeting of the new central committee to meet at the offices of the department.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

PERMANENT ARTERIAL HYPERTENSION—TREATMENT OF INFECTION BY INTRAMUSCULAR INJECTIONS OF MERCURY—SCHLEICH'S ANESTHESIA—DEATH CAUSED BY ANTITETANIC SERUM—TREATMENT OF THE MORPHINE HABIT.

PARIS, May 30, 1912.

AT a recent meeting of the Academy of Medicine Fiessinger read a paper on permanent arterial tension not infrequently observed in the subject of arteriosclerosis who may have no apparent functional lesion of the kidneys, in the obese, and in those suffering from asystole. In subjects of this kind one often sees temporary crises of high blood-pressure brought about by some extra exertion, a hearty meal, a long railway journey, or fatigue arising from any cause. The treatment of these crises consists in a milk diet, or at least the avoidance of meat, in rest in bed, and in a strict observance of all hygienic rules. The high frequency current is of use only in these temporary attacks but does not reduce permanent or chronic hypertension. The hypertension encountered in the obese calls for the same treatment as the obesity itself; when the patient's flesh is reduced his blood-pressure will fall at the same time. In the arterial hypertension of asystole minute doses of digitalis combined with theobromine will give excellent results. Thus the curable forms of chronic arterial hypertension are those in which one is able to cure the causes of high blood-pressure, as in obesity and asystole. Treatment is of value only in the crisis which yield to diet and rest, but even with a high blood-pressure patients may live many years if they will avoid excesses of all kinds which may open the door to cerebral accidents or renal insufficiency.

An interesting discussion took place recently at a meeting of the Société de Chirurgie on the treatment of infection by intramuscular injections of mercury. Souligoux related his experience with this method in the treatment chiefly of puerperal infection. He injected daily for seven days a solution of 1 cg. each of cyanide of mercury and stovaine in 1 c.c. of distilled water. Of 144 patients so treated the author lost but three, and on the strength of this showing urges the use of mercury in all cases of systemic infection, the only contraindication being renal insufficiency.

At the same meeting Jean Louis Faure read a paper on the induction of general anesthesia by Schleich's mixture of ethyl chloride 10, chloroform 20, and ether 60. He regarded it as greatly superior to chloroform alone, for he had never seen any heart trouble due to it, and postanesthetic vomiting rarely, if ever, occurred.

A case of death following an injection of antitetanic serum was reported by Riche. The serum was obtained from the Pasteur Institute and was given hypodermically in dose of 10 c.c. The speaker regarded this as an exceptional case, the general experience up to the present having been that the use of antitetanic serum was innocuous. Jacob said that one instance of this sort should not be allowed to weigh against the employment of so valuable a prophylactic. The preventive action of antitetanic serum had been conclusively demonstrated in military practice. Whenever the serum had not been employed, as in the Madagascar war, tetanus prevailed largely; where it was habitually used, as in the Morocco campaign, tetanus was practically non-existent, the only cases observed being in those exceptional instances in which for one reason or another a prophylactic injection had not been given. Arrou said his experience with the antitetanic serum had been uniformly favorable. He made it a rule to give a prophylactic injection in all cases of lacerated or punctured wounds and for eleven years past he had had no case of tetanus in his practice. Reynier was not quite so optimistic as the previous speakers, for he said the serum was not always so innocuous as surgeons in general were inclined to think. Nevertheless the undoubted prophylactic value so far outweighed the possible accidents that one would not be justified in withholding the serum in cases of lacerated wounds.

At a recent meeting of the Société de Médecine Maurice Page read a paper on the treatment of morphine addition. Sudden deprivation was dangerous, he said, and apt to induce syncope and fatal collapse. The substitutive method by giving other narcotics was worse than useless, for it resulted merely in a succession of weanings from drug habits without arriving at any end. Gradual suppression was without suffering, but it was ineffective unless the patient was under constant and complete control. Rapid suppression, in the course of eight or ten days, is favored by Sollier. This, however, causes much distress and measures must be instituted to calm the patient. Active purgation is called for, and baths—of water, light, and electricity—under excellent service. Among drugs are to be recommended sparteine sulphate, ammonium valerianate, and bromides.

OUR LETTER FROM THE PHILIPPINES.

(From our Regular Correspondent.)

VAGARIES OF LIGHTNING—DEATHS FROM LIGHTNING IN THE PHILIPPINES—CENSUS OF MIDWIVES—POSTGRADUATE COURSE IN TROPICAL MEDICINE—SANITARY ORGANIZATION IN THE PHILIPPINES.

MANILA, P. I., May 31, 1912.

A MOST unusual instance of lightning stroke occurred in the town of Cervantes, in the province of Lepanto, on May 2. During a light thunder storm a bolt of lightning entered the middle of a grass roof near the comb and passed down the center supporting post of the building and killed a young man, aged 18, and a girl, aged 12, who were sitting on a bamboo couch near an open window. The father of the two children, who was sitting on the ground nearby, was stunned by the electrical charge, but soon recovered. The victims both showed burning of the hair of the scalp on the side of the head, the burned area being, approximately, an inch in diameter. No other marks or disfigurement could be found. Three hours after the accident no post-mortem rigor had set in.

The building in which these persons were killed is a low, grass shack, approximately 8 x 10 x 8 feet; the sides or walls are constructed of nipa palm; the roof is made entirely of grass and is nearly a foot in thickness, and the building is located in an open, treeless field about a kilometer and a half from the center of the town. There are no habitations or houses of any kind within a distance of four hundred yards. A fish pond, 20 x 40 feet, with water a few feet deep, is located within fifty feet of the house. Another child, who was playing outside, near the house, did not notice anything unusual about the lightning, nor did she know that anything had happened to the occupants of the house until about ten minutes later, when she entered the building. It seems, indeed, most singular, that a low building which is built of such non-conducting materials as are enumerated above should have a lightning bolt pass through a foot of dry grass, select the middle post, pass down this and kill two persons who were, perhaps, five feet away at the time. It is curious to note, however, that this middle post was of a wood known as tebbeg, and entirely different from the wood which composed the other supporting posts of the roof. The lightning split the post badly, and the explosion which took place caused splinters, some of which were a foot long, to be hurled in all directions. It was possible to pull many of them out of the walls of the house, where they had embedded themselves.

In this connection it may be interesting to observe that during the past five years deaths from lightning in the Philippine Islands have been reported as follows: 1907, 42; 1908, 34; 1909, 71; 1910, 47; 1911, 30.

This gives an average incidence of 45 deaths from this cause per annum, and as the population of the Philippines is, in round numbers, 7,000,000, it will be observed that there is one death from lightning stroke annually among every 155,556 of population. The United States census shows that in the United States there is one case of death from lightning stroke among every 333,333 of population. In view of the fact that thunder storms prevail during eight months of the year in the Philippines, and only, approximately, four months in the United States, it will be seen that the incidence is about the same. In further analyzing the figures of deaths from lightning stroke throughout the Philippine Islands it is interesting to observe that the deaths are fairly evenly distributed throughout the archipelago. The majority of the deaths, however, occur in provinces which are on islands which have the largest area. The smaller islands, like Bohol, Masbate and Romblon, which have areas less than 1,600 square miles, have not reported any deaths from this cause.

Recently a complete census of the midwives in Manila was made by the Bureau of Health, and also an investigation of their fitness and training. It was found that there were 66 midwives who regularly carried on this vocation. Of this number 41 had no license whatsoever, and invariably their personal cleanliness and the cleanliness of the houses in which they lived was much more unsatisfactory than among the licensed midwives. It is very difficult to deal with the unlicensed midwives in a legal way, because no penalty attaches unless it can be shown that they receive a fee for their services, and this has been difficult to demonstrate in the past to the satisfaction of a court. In order to overcome this difficulty the Manila Medical Society has drafted a law for consideration by the Legislature which makes it illegal to practise midwifery without a license, whether the woman charges a fee for her work or not.

The College of Medicine and Surgery of the University of the Philippines is just about to start a postgraduate course in tropical medicine and in public health. The degree of Doctor of Tropical Medicine is to be granted after the satisfactory completion of a one-year postgraduate course in tropical medicine, and the degree of Doctor of Public Health after the satisfactory completion of the first year postgraduate course in tropical medicine, and a second year course in public health. The enormous amount of clinical material available in the city of Manila, as well as the facilities afforded by the very modern Philippine General Hospital, and the large number of trained scientific workers who are connected with the University, affords the school unusual opportunities for giving a first-class course in these branches.

Sanitary organization and its practical application has probably reached a higher degree of development in the Philippine Islands than is the case elsewhere. The success which has attended the application of hygienic and sanitary measures has fully justified the plans under which it was achieved, and the laws by which it was brought about are, therefore, of great interest. The Sanitary Code for the City of Manila is one of the few ordinances in existence which covers the whole field of municipal hygiene and sanitation. The course in public health will offer innumerable opportunities to observe the actual workings of this law. On account of Manila's close proximity to the great infected centers of the Orient there are more opportunities for studying modern maritime quarantine methods and witnessing their application than is the case elsewhere. The large Mariveles Quarantine Station has treated more infected vessels in recent years than any other similar station in the world. The questions connected with better water supplies in the tropics, with a view to their solution, have received a vast amount of attention and extensive laboratory studies are constantly in progress. On account of the rapid development of the islands many occasions are constantly afforded for observing the installation of the different kinds of water systems and noting their effect upon public health. There will be ample opportunity to become familiar with the laboratory examinations connected with the analysis of foods and drugs in connection with the enforcement of the Food and Drugs Act. The new developments in public health work are constantly being applied in the Philippines on a large scale, so that the testing of the new theories of sanitary science by practical application may be constantly witnessed and their value determined.

From the foregoing it is evident that the postgraduate course outlined offers opportunities of the very highest order which should secure interest and students from universities not so favorably situated. Students who are graduates of the College of Medicine and Surgery will be admitted free of charge. Those who are not graduates of this institution will be obliged to pay a fee of $125 per school year.

Alvin J. Cox, formerly Chief of the Division of Inorganic Chemistry, Bureau of Science, has been appointed Acting Director of that Bureau, and Henry D. Gibbs, formerly Chief of the Division of Organic Chemistry, has been appointed Acting Assistant Director.

Progress of Medical Science.

Boston Medical and Surgical Journal.

July 25, 1912.

1. Second Note on Bacterial Invasion of the Blood and the Cerebrospinal Fluid by Way of Lymph Nodes: Findings in Bronchial and Retroperitoneal Lymph Nodes. E. E. Southard and M. M. Canavan.
2. Immigration and the Midwife Problem. I. S. Wile.
3. The Efficiency of the Operative Population of a Textile City as Viewed from a Surgical Standpoint. M. B. Swift.
4. Institutional Dentistry. Methods. Results. F. A. Keyes.
5. The Massachusetts Reformatory Method of Differentiating Defective Delinquents. G. G. Fernald.

1. Invasion of Cerebrospinal Fluid by Way of Lymph Nodes.—E. E. Southard and M. M. Canavan, following the same technique adopted by Gay and Southard in their study of the post-mortem bacteriology of the blood and cerebrospinal fluid, and that of Southard and Canavan in their study of the blood, cerebrospinal fluid and mesenteric lymph nodes have studied the post-mortem bacteriology of further cases, replacing mesenteric by bronchial lymph nodes, and in other cases adding retroperitoneal lymph nodes. The conclusion of two former papers is further established, viz., that post-mortem cultures from the cerebrospinal fluid are more likely to yield growths than cultures from the blood. Just as the cerebrospinal fluid proved more frequently positive than did the mesenteric lymph nodes, so, too, the fluid remained more frequently positive than the bronchial lymph nodes. Retroperitoneal lymph nodes, however, were found more frequently invaded than either blood or cerebrospinal fluid in the authors' series.

2. Immigration and the Midwife Problem.—I. S. Wile states that in order to appreciate the relation of immigration to midwifery, it is necessary to ascertain how many midwives are admitted to this country. In order to protect the country from the unscrupulous midwife, it is essential that a system of education, supervision and control be established throughout the various States of the Union. Only by education and legislation and by controlling the immigrant midwife will it be possible to prevent an increase of the dangers now attributed to midwifery among the constantly increasing immigrant population. The increase in midwives depends upon the increase of female immigation. The standards of midwifery in this country should be raised at least to the standards existent in the countries from which the immigrant midwife comes. By the further control of immigation and the securing of information relating to the educational, professional and legal status of midwives, it will be possible to place the midwife problem in an intelligent manner before the American public.

3. Surgical Aspects of the Textile Industry.—M. B. Swift notes that in Massachusetts the permanent loss of efficiency due to the textile industry is small. This is due in part to the laws which govern the industry, and to the care used voluntarily by the employers and employees. The hours of labor have little or no bearing on injuries, as these injuries happen with about equal frequency at all hours of the day. Temporary loss of efficiency is considerable, not necessarily because of the severity of the injuries, but rather because of the care necessary in the treatment of the injuries to ward off the effects of infection. The open antiseptic treatment of the open wounds is the only logical treatment, and produces most excellent results in maintaining the efficiency of the industry. The cotton manufactories in Massachusetts do not cause as great a loss of efficiency to the community as do the other mechanical trades

1. The Tissue Density Factor.—H. Wakefield believes that throughout the body the tissue density factor is an important one in various respects. In relation to the circulation the loss of the vascular tonicity of expanded and flabby tissue is familiar to all. Dilated vascular walls imply a passive hyperemia and a sluggish circulation. Elongated muscles, ligaments, and aponeuroses imply weakness, incoordination, and general incapacity. The relation of tissue density to its permeability is one of great importance. The exudation in progressive order of water, serum, and blood from rarefied tissues is common in pathological cases, and edemas, hemorrhagic extravasations, and purpuras are not infrequent in some advanced cases. Rarefied cells and dilated interstices, low surface tension, and osmotic pressure, are responsible for innumerable deposits in such tissues of urates, oxalates, and tissue and blood detritus and pigments, as well as bacteria. The problem of susceptibility to infection is closely related to the density of tissue as regards invasion, favorable soil, vital resistance, reaction weakness, impaired oxidation, autolytic powers, and all the other factors which go to make up the prophylactic capacity of high tissue integrity. The selective determination to, and action upon the diseased tissues by the dyes recently introduced into therapeutics, must depend upon the difference of surface tension and osmotic pressure.

5. Mercuric Salicylate Intramuscular Injections in Syphilis.—J. L. Wollheim states that the injection of the insoluble mercury suspensions causes indurations. Quinine and urea alleviate in many cases the pain and discomfort caused by most of the mercury salicylate suspensions. Quinine and urea hydrochloride is nontoxic and does not impair the therapeutic action of mercury.

7. Iodine as a Surgical Disinfectant.—F. T. Woodbury discusses the essential and indispensable properties which a substance must possess in order to be a surgical disinfectant. It must be bactericidal in simple solutions with harmless liquids. It must form solutions with great osmotic power; that is, with power to penetrate and reach the deep-seated bacteria. The solutions of this substance must not be poisonous in bactericidal strength. The solutions must be equally bactericidal in any accessible infection in any tissue of the body. The disinfectant must not be histolytic, even on debilitated tissue, but should favor cellular recuperation and organization when in solutions of sufficient strength. It must have prophylactic power when used before any symptoms of infection have appeared. The solutions of this substance must be simple in formula and easy to prepare. The substance in antiseptic solution must be cheap. It must be readily obtainable. It must be readily and safely transportable in ordinary containers without deterioration. It should not be irritating to those using it, nor form compounds with other chemicals used in surgery, which may be dangerous. With these points in view, one may reasonably entertain the belief that iodine (and particularly the two per cent. alcoholic tincture and the five per cent. watery solution) comes nearest to fulfilling the requirements of surgical disinfection of any of the substances offered for that purpose.

1. **The Menace of Plague.**—H. D. King states that plague is a menace to the United States at the present time. The present pandemic is not merely unchecked but is really growing greater daily, as shown by its occurrence in Cuba and Porto Rico. It has followed commercial routes, but largely by sea as against the overland commercial routes of former pandemics. It is not limited by continents or latitudes or longitude, but can become epidemic in any part of the world under favoring local conditions. Certain peculiarities of this pandemic are worthy of note, such as variations in susceptibility, and in the virulence of the disease in certain areas. The most dangerous fact is the tendency of the diseases to remain dormant in certain localities only to recur sporadically. This leads to a false security and the disease may insidiously establish new foci of infection. Nowhere are these peculiarities more manifest than in South America, which may be considered as the occidental distributing center at the present time. The present danger is from without, but it is very close, and if the plague should reach the country King believes it will be through some Gulf or South Atlantic port. The entire west coast of South America is infected and its eastern coast in spots, from one of which it has spread to Porto Rico and Cuba. In no South American country is there a properly constituted board of health. There is a lack of cooperation between the state and local boards. Maritime sanitation is very imperfect and the means of combating plague are inadequate and antiquated. The character of the exports is also to be considered and the importation of rodent furs, such as chinchilla, may be a means of carrying infection. The above strictures do not apply to capital cities, like Rio, Buenos Ayres, and Valparaiso. The author credits the smuggling and coasting traders between the West Indies and South America with the introduction of the plague to Cuba and Porto Rico.

4. **Pelvic Drainage.**—J. Wesley Bovée notes that the indications for drainage of the pelvic portion of the peritoneum are (1) the suspected presence of infectious materials, such as pus or serum or infected blood-clots of ovarian, uterine or tubal hemorrhages caused by ectopic pregnancy or other conditions; (2) capillary hemorrhages and denuded areas resulting from separation of broad adhesions between the remaining pelvic structures and the uterus, pelvis, Fallopian tubes, and ovaries or neoplasms of the same; and (3) injuries of the rectum, lower ureter or bladder resulting usually from operations on the adnexa or on those structures themselves by the transperitoneal route, from which sites subsequent leakage may be feared.

5. **Tumors of the Small Intestine.**—By W. D. Haggard. (See MEDICAL RECORD, June 29, 1912, page 1246.)

6. **Benign Epithelioma.**—M. L. Heidingsfeld questions the commonly held opinion that skin diseases afford special advantages for the study of morphological changes incident to malignancy. No malignant tumor of the skin can attain sufficient size to permit macroscopic recognition and at the same time demonstrate its genesis and origin from some definite follicle, gland or epidermal structure. There is, however, a certain class of skin tumors, the so-called multiple benignant systic epitheliomas, which present some unusual features for study. Five cases of this type are discussed as regards their morphology. The author has also included in his consideration a case of morphea-like epithelioma and a case of carcinoma epitheliale cicatrisans on account of certain features they afford for comparative study. The conclusion that he reaches is that the genesis and fundamental origin of all forms of epithelioma must, in the light of present knowledge, remain a more or less unsettled question. While it is clinically true that moles, etc., sometimes take on malignancy the vast majority show no such etiology. If malignancy starts from hair follicles, sweat glands and other preformed cellular structures, cases should be more frequent than are currently reported.

8. **Chronic Unopened Empyema.**—By E. M. Von Eberts. (See MEDICAL RECORD, June 29, 1912, page 1245.)

9. **Surgery of Chronic Infectious Diseases of the Lung.**—By S. Robinson. (See MEDICAL RECORD, June 29, 1912, page 1245.)

10. **Survival of the Poliomyelitic Virus in the Stomach and Intestines.**—S. Flexner, P. F. Clark, and A. R. Dochez conclude from their experiments that the poliomyelitis virus occurs in the nasal and buccal mucus in human cases of poliomyelitis and it is inevitably taken into the stomach with the swallowed saliva. The virus survives the action of both the gastric and intestinal secretions and persists for a time in these organs. In human beings it leaves the body, in part, with the intestinal discharges, which are therefore a potential source of infection. It remains to be determined whether in the monkey artificially fed with the virus it also passes out in a viable state with the dejecta.

11. **Myositis Ossificans Traumatica.**—St. C. Vance notes that there are two forms of myositis ossificans—progressive and traumatic. The progressive form is a rare disease of early life tending to ankylosis of all articulations. Traumatic ossifying myositis follows one of two kinds of injuries. The trauma may be a slight one and frequently repeated, and such cases are occasionally seen in cavalrymen, in whom the adductor muscles undergo sprain from overuse, resulting in what is called "rider's bone." In the other type the trauma may be a single severe one. The theory is that blood and possibly a number of displaced periosteal cells infiltrate the muscular connective tissue and organize into the bony structure. The salient points of a case reported by the author are the formation of the tumor in nine weeks, its location in the crureus muscle and the early excision and complete relief of disability.

7. Observations on the Neuron. H. Campbell.

1. **Intractable Constipation Treated by Operation.**—P. Lockhart Mummery states that one can recognize three distinct types of constipation: (1) Obstructive constipation, in which some definite obstruction exists to the passage of fecal material along the colon; (2) atonic constipation, in which the peristaltic and expulsive power

of the colon is deficient; (3) undue solidity of the fecal material interfering with its passage along the colon. The cases of obstructive constipation form the majority of the cases brought to the surgeon and are those which in most instances can be treated successfully only by surgical operation. Adhesions constituted one of the commonest causes in the author's series, being present in eight out of a total of thirty cases. Cases due to adhesions are generally characterized by well localized pain in the abdomen, which is especially noticed at the time when peristalsis is active—that is to say, two or three hours after a meal and before the bowels act. The pain, in a few cases, is very severe, and is then probably the result of enterospasm in the section of bowel just above the kink. The essential factors which make for success in operations for localized adhesions are: (1) perfect asepsis; (2) doing the operation bloodlessly, and particularly leaving no blood in the peritoneal cavity; (3) covering in all raw surfaces and stumps by careful suturing, and, where necessary, by plastic operations on the peritoneum; and (4) gentle handling of the peritoneum. Of all the cases in the author's series those of visceroptosis and atony of the bowel were the least satisfactory. According to the author's experience there is no surgical treatment which can be depended upon to cure these cases. Appendicostomy, by enabling the bowel to be kept empty, gets rid of the autointoxication, which is one of the most serious symptoms, and therefore gives considerable relief, but the author cannot say that appendicostomy entirely cures these cases.

3. **Treatment of Diphtheria Infection by Means of Diphtheria Endotoxin.**—By R. T. Hewlett and A. T. Nankivell. (See page 252.)

5. **Relation of Iron to Anemia in Infancy and Childhood.**—H. T. Ashby states that the liver is the organ that has most to do with the storage and with the metabolism of iron. The liver in intrauterine life receives a very good blood-supply by means of the branches of the umbilical vein carrying arterial blood from the placenta. It seems that the liver performs a similar storage function with regard to iron as it does with regard to fats and carbohydrates. As in animals, the human being has iron stored up in the liver at birth to last while the individual is being fed on the milk, which is almost devoid of iron. A full-term fetal liver contained five times as much iron as the adult liver, and as much as one from a case of pernicious anemia. Most of the livers from children contained more iron than the adult ones, but the iron in the livers of the infants gradually diminishes as they grow up, which would be expected. The liver of a rheumatism case contained practically no iron, a fact that is interesting when it is known how pale the child was and that she died from the effects of rheumatism with peri- and endocarditis. In this case there must have been a great destruction or else an inhibition of the renewing of the red blood cells. A case of Hodgkin's disease, in which there had been anemia for a long time, also had very little iron; on the other hand, the splenomedullary leucocythemia, which had great anemia, contained a fair quantity of iron. These last two cases had had large quantities of iron given them during the disease, but it must have been nearly all eliminated as soon as it was taken, or, at any rate, was not stored in the liver. The two cases of pernicious anemia contained a large quantity of iron, which was in the form of inorganic iron, unlike the other livers, and the iron could thus be stained at once without unmasking. A case of hypertrophic cirrhosis also contained a large quantity, and after the piece of liver had been burnt away in the crucible the iron could be seen quite clearly as a red residue. No doubt the iron in pernicious anemia is in such a state that it cannot be used, or else the body is unable to use it for some reason.

1. **Operations for Cancer of the Tongue.**—W. G. Spencer states that the late Sir Henry Butlin taught that the excision of any persistent patch or indolent ulcer is the means for preventing the onset of cancer of the tongue. The operation is quite safe, is not followed by any deformity, and as soon as the tissue removed has been examined the patient may be assured of safety. Further, the early excision of an epithelioma of the tongue, followed by excision of the glands in the neck, is for early cases not dangerous, and in Butlin's hands as many as 42 per cent. of such were alive and free from recurrence three years after the operation. If these cases are advised to submit to early operation one will not have to regret that they will reach an advanced stage, when severe, deforming operations become necessary. Yet one might quote any number of single cases, which have been exhibited by various surgeons, alive and well more than three years after such operation. Sir Henry Butlin made a great advance; there is a need for much more. As he remarked, the majority of cases operated upon die of the disease, and the Registrar-General's statistics state that more than 750 people die annually in England and Wales of cancer of the tongue.

2. **Oxygenation and Tuberculosis.**—B. Moore states that the tubercle mass is non-vascular and perishes and caseates as it grows in size for lack of oxygen. The giant multinucleated cells which it contains probably owe their form and development to lack of oxygen—at least that is the type of result which is seen when young growing cells are partially asphyxiated. The tubercle bacilli in a tubercle are in a situation where they are in a minimum concentration of oxygen. First of all they are in relationship to the lymphatic system, where outside them the oxygen supply is at its poorest; and then, in addition, they are separated from the lymph by a non-vascular area which increases in size as the tubercle grows. This is a favorable condition of growth, and when the tubercle breaks down the live bacteria are discharged to find new points at which to start more tubercle formation. The well recognized treatment of tuberculous joints by the hyperemic method of Bier is interesting from this point of view; the increased capillary pressure leads to increased lymph flow, and so does artificially for the joint what mitral stenosis does for the lung. The beneficial results of the Finsen light treatment upon lupus are also commonly ascribed to the local hyperemia induced in the affected area. If this be so, it is an additional argument in favor of the view that increased oxygenation of the surrounding lymph is the beneficial agent, for the increased blood supply and blood pressure in the capillaries will lead to increased lymph flow, and hence to increased oxygenation of the affected area. The treatment of phthisis by open-air methods and by high altitudes is also in accord with this view, upon which the effect obtained would in both cases be due to a common cause—namely, the more efficient ventilation of the lung, and, as a result, the mechanical increase of the lymph flow, especially at the apices.

4. **Intratracheal Insufflation Anesthesia.**—R. E. Kelly summarizes the advantages of this method as follows: The current of air at the glottis is outwards. The air enters through the catheter and escapes between the catheter and the opening of the glottis. Against this cur-

rent no blood, mucus, or vomitus can possibly find its way into the air passages, so that in difficult mouth, tongue, jaw, and goiter operations, or cases of intestinal obstruction, there is not the slightest danger of any foreign material gaining entrance to the lungs. In mouth and neck operations the surgeon is in no way interfered with by the hands of the anesthetist, for a tube alone connects the patient with the apparatus, which may therefore be placed at any distance from the operating table. In those diseases in which respiration fails life can still be maintained. It is possible to give a dog twice the lethal dose of strychnine and yet keep him alive in spite of the spasm of the respiratory muscles. In a case of myasthenia gravis, reported by Elsberg, in which respiration failed on account of paralysis of the respiratory muscles, a patient was kept alive for some twelve hours after all normal respiratory movements had ceased. There is no doubt that in the future, whenever available, this method will replace the present system of artificial respiration by manual means, especially in cases of poisoning and tetanus. Chest surgery now becomes practicable in the absence of either a Sauerbruch or Meyer cabinet. The author has employed this method of anesthesia in twenty-five cases and has found that the patients recover more quickly, the after-effects are lessened, vomiting has only been noticed once, and from the surgeon's point of view the anesthesia is perfect. Further, the anesthetist has a greater sense of security, for if at any time he thinks that artificial respiration may be necessary, he has the apparatus ready at hand, and has merely to turn the pointer from "ether" to "air."

7. **Gastric Adhesions as a Cause of Sudden Death.**—By G. H. Winch. (See page 267.)

Berliner klinische Wochenschrift.

July 15 and 22, 1912.

Method of Testing the Functions of the Pancreas.—Ehrmann states that in testing the activity of the pancreas enzymes by the work they do, as shown chemically and microscopically by a study of the siphonates and feces we always have to discount the effects of gastric digestion. The methods in use for this purpose are slow and uncertain. The author has devised or discovered a color reaction which will enable one at a glance to estimate the work of the pancreas. It is known that neutral fat free from fatty acid is split up solely by the pancreas lipase and that the resulting acids form green salts with copper. Commercial palmin makes a good neutral fat for testing. None of the ordinary dietetic fats is suitable for this purpose. On a fasting stomach the patient takes the following trial meal: About thirty grains of rice flour are dissolved in a quarter liter of water, warmed, and a little salt added to give sapidity. Some seventy-five grams of palmin are liquefied and stirred in. The mixture is then swallowed and allowed to remain for two to two and a half hours, when it is siphoned out. The siphonate is shaken up with petroleum ether containing 10 per cent. benzol and the ethereal extract of fat is then mixed with a solution of 3 per cent. acetate of copper. The activity of the pancreas is indicated by a brilliant emerald green. If the pancreas lipase is absent no color change results. If there is a certain per cent. of HCl in the siphonate, as shown by Congo red, the test may fail. But it may be obtained in a second attempt in which soda is added to the test meal.

Pregnancy After Artificial Impregnation.—Hirsch, apropos of Döderlein's recent success in this field, speaks of the popular sensation caused by its publication, as if it was something novel. The author believes that the small number of published cases gives us no idea of the vogue of the practice. The art itself is so simple as to suggest itself to any practitioner, and of those who practiced it some certainly would not, for one reason or another, be likely to report it. The author knows of successful cases which not only were never published, but were known to very few people. The author himself has had not less than sixteen cases, of which number six were successful. In the first case three attempts were made and the third succeeded. The woman was perfectly normal, and the cause of failure of natural impregnation was not apparent. In the second case the cervix had been dilated and a false position of the uterus corrected before impregnation could be effected. On account of the tendency to retroflexion, the woman aborted. One of the other women had a small uterus, but impregnation resulted. In one of the six cases the fault lay with the husband whose potency was weak. The author's technique varies in no wise from the common practice. Timidity or modesty is the greatest obstacle to success, and the privacy of the home must be secured, although Doderlein's recent case transpired in the hospital. The author would never consent to use semen from another man, a possibility which has sometimes been debated.

Leucemia and Benzol.—Von Korányi refers to the cases reported by Barker of workers in benzol who developed severest anemia and purpura. As a result, Selling made experiments and found that in rabbits benzol first increased and then diminished the number of leucocytes until they disappeared altogether. This fact suggests that benzol might be of value in leucemia and the present author at once exhibited it to a number of patients with that affection. The blood counts show surprising improvement. The action of benzol is slower but more certain than that of the *x*-rays. A good initial result was obtained in a case of polycythemia with enlarged spleen. It is as yet too soon to pronounce on ultimate results. Three or four grams of benzol are the daily dose.

Researches with Tumoraffin Substances.—Neuberg, Caspari and Löhe report progress in researches into tumor therapy in animals. Neuberg sums up his section with the statement that several substances have been discovered which exert a selective action on cancer and sarcoma cells in mice, rats and dogs, destroying them in the living animal. Two classes of substances are concerned, selenium plus coloring matters and the tumoraffin metals. Caspari cited a number of cases of brilliant results. Since various substances were used, no one receives special designation. Simply some tumoraffin substance is injected into the caudal vein of the rat. Löhe, who studied all the tumors in order to determine the rationale of the action of remedies, mentions among the latter tin, lead, arsenic, copper and so on through most of the metals. The result is a softening of the center of the mass as a result of the affinity of the metal for the tumor cell. In the present experimental stage of the research no technique is given The tumoraffin principle has in a measure been foreshadowed in the employment of metallic iodides in gummata; and it is announced that sodium iodide has some inhibiting power over mouse tumors.

Late Eunuchism and Multiple Bloodgland Sclerosis.—Falta of v. Noorden's classic describes a condition which while new in a sense may be recognized from descriptions of historical episodes—for example the state of eunuchism which developed in some of Napoleon's soldiers in the Egyptian campaign. This metamorphosis has always been a mystery, but quite recently the same condition has actually been described by Gandy, whose name it goes by and who accounts for it by dysthryoidism while others accuse all the endocrinic glands. It is less an unsexing than a reversive infantilism, and instead of being a clean cut condition is doubtless a very composite affection. The initial factor in Napoleon's cases was probably gonorrheal and syphilitic orchitis, but other causal factors must have been superadded for it is known that these affections seldom destroy the testicles. Traumatism involving the tes-

ticles has produced the picture. In other cases no cause is apparent. A close study shows that atrophy of the testicles can by no means illuminate the condition. There is a complete involution of these bodies and this in some measures causes disappearance of sexual desire and secondary sexual characters. The symptomatology is therefore closely allied to the results of castration. The article will be continued.

Increase in Dietetic Protein as a Galactagogue.—Liepmann shows that by adding concentrated protein to the ordinary diet of nursing animals the total quantity of breast milk is increased. The discovery is by no means new, having been announced about 1900. The author in order the better to demonstrate its truth or falsity tested it upon goats. The finds were so positive in character that he will transfer his research to women. The substances for reinforcing the diet protein were some of the casein albumoses.

Münchener medizinsche Wochenschrift.

July 9 and 16, 1912.

Ergotin and Caffein in Myocarditis, Arteriosclerosis, and Cardiac Neuroses.—Weile, who has already advocated the combination of the two remedial principles for these affections, adds that he has now treated twenty cases in this manner. He gives a typical example in which the patient had become unable to earn his livelihood. The patient was a young man, and nothing could be found to explain the prostration and constant vertigo of which he complained beyond the fact that the fifteenth heartbeat was regularly skipped. The two remedies were injected in the precordial area, and the missed beat was at first deferred and eventually became wholly normal. The patient's strength was regained and he was able to resume work. The subcutaneous injections were alternated every second or third day with the internal exhibition and treatment was maintained for five or six weeks. After cessation of treatment there has been no relapse, although this case goes back ten years. The author cites a parallel case, untreated, which appears to show that these cases of cardiac neurosis may end in fatal collapse. The case has been regarded as one of hysterical vertigo. In another case treated by the author's method the patient, a man aged 65, had advanced arteriosclerosis. The heart skipped every eighth or tenth beat. The remedies were given internally. The heart action became normal, but the arteriosclerosis had gone beyond the point at which it could be influenced by treatment.

Undesired Collateral Action of Hypophysis Extract.—Bovermann reports a case in which after evacuation of the uterus after abortion hypophysis extract and ergotin were given for hemostasis. As patient came out of the mild ether narcosis she complained of abdominal pain. The pulse was very poor and soon afterwards the woman collapsed. Hemorrhage had wholly ceased. The usual analeptics seemed inert, but intravenous saline infusion produced a reaction. Only after some hours did she revive fully. Ergotin has produced this result in very large doses, but in this case only the usual single dose was given. The condition is best explained by synergism of two drugs which alike cause contraction of the blood vessels. The patient had lost much blood and the condition should be regarded as an extremely protracted syncope.

The Luetin Reaction.—Kämmerer of Munich has just finished testing a series of a hundred and more cases. His conclusions to date are as follows: There is neither danger nor unusual discomfort to the patient. In the material tested, with a solitary exception, the reaction was proved to be specific for syphilis. It is not always possible to distinguish a specific local reaction from a nonspecific, accidental consequence of the injection. Controls sometimes show vesicles and pustules. In over one-half of the known syphilitics the reaction was negative. Late cases seem more disposed than early ones to give positive reaction. The numerous negative results may be explained in part by the state of the allergy and partly by a denaturing of the spirochete albumin. Two weeks' observation are required to control the cases of so-called torpid reaction. The luetin reaction is of use to supplement the Wassermann reaction, and is so much more elementary that any practitioner may use it himself. As to the best methods of preserving the spirochete extract there is considerable uncertainty.

Surgical Prophylaxis of Acute Coryza.—Sick refers chiefly to the disturbing influence of a severe cold in connection with surgical work. Operations cannot be deferred. The surgeon or assistant may wear a veil, but this is unpromising as a resource. Diseases like erysipelas may be conveyed from a cold, for the bearer may have infectious sinus disease. To so slight a cause may be traced the failure of wounds to heal by first intention. An analogous problem is that of the pediatrist with a fresh cold who must come in contact with nurslings. In common or influenzal coryza one pediatrist snuffs up a few drops of lysoform from his palm just before visiting a nursling ward. It causes pain and a free discharge from nose and pharynx but is soon followed by relief. Incidentally it was learned that a cold could be jugulated in this manner, by snuffing the lysoform four or five times at two to four hour intervals. The author made trial of this expedient but in his case at least the result was not so fortunate. Some years ago various drugs, menthol, camphor, eucalyptus, protargol, etc., were tried out for this same purpose. The methods, however, were too little adapted to the task of rapidly sterilizing a surgeon's nose. There is nothing absolutely new in this sort of prophylaxis, for it was used long ago by medical men in influenza years. Experiences under such conditions are largely personal and not necessarily transferable. In 1904 and 1906 the present author suffered much from influenza, catching cold at the least exposure. He made extensive use of aspirin during these periods. On account of the tendency to contract fresh cold at night the author took an evening dose and usually waked up clear. At any time when he felt the preliminary sensations, he took one or two doses of a gram each. Much depends on proper timing. As an operating surgeon the author has solved the problem as far as it relates to himself.

Cause of Scoliosis.—Port opposes the view that scoliosis can be due necessarily to want of muscular equilibrium from faulty posture. He relates the case of a ten year old child, strong and muscular, of sound stock, no rickets, which he had often seen undressed and admired as faultless in development. The boy then began to complain of headache and the nuchal muscles were found to be tender. The pains yielded promptly to aspirin. Examination showed no further anomalies. A few months later lateral curvature was evident. From this and a parallel case the author concludes that scoliosis may develop suddenly in the midst of robust health. There was absolutely no history of a faulty posture. The trouble was attributed to a primary myopathy which affected the muscular equilibrium. The myopathy would be termed an insidious, chronic muscular rheumatism.

Trophoneurotic Separation of Nails, Followed by Alopecia Areata.—F. Parkes Weber reports the case of a woman, aged thirty-seven, in whom these associated conditions were present. In March, 1911, a skin eruption had appeared on her hands and fingers, and deep grooves like exaggerated "Beau's lines" had formed. Somewhat later the toenails were affected similarly, but to a lesser degree. Under mild arsenical treatment the abnormal condition of the nails disappeared; but in March, 1912, alopecia areata of the back of the hairy scalp commenced to be noticed.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

THE NERVOUS SYSTEM.—It is safe to state that the condition of the nervous system receives too little attention in the great majority of examinations for life insurance. Specialists in nervous diseases have assured life insurance medical officers that they could almost guarantee to furnish applicants who would pass the usual examination for life insurance and yet whose acceptance would prove a loss to the company, some within a very short time. This statement refers especially to cases of general paralysis of the insane and tabes dorsalis in their incipient stages. Examiners should always, then, have in mind the possibility of meeting with one of the dangerous forms of nervous trouble in its early stage when the signs, though most important, are slight and easily overlooked.

Subjects with marked or advanced disease of the nervous system will rarely present themselves for examination. Not infrequently, however, applicants having atrophy of one or more of the extremities with some deformity and a moderate degree of disability, the result of acute poliomyelitis in early life, will be encountered. This condition is of little consequence unless very marked, and the examiner's duty in such cases ends with including a full description in his report and leaving the question of acceptance to the home office.

The following signs and conditions are most important:

The Facies.—The facial aspect and general behavior of the applicant may occasionally afford some information. Bell's paralysis, if present, would only cause postponement of the risk until full recovery; but the examiner should make sure that the condition is a peripheral one, and not due to a central lesion or middle ear disease.

The Eyes.—Report inequalities of the pupils, and state whether they are unduly dilated or contracted. Marked inequality of the pupils may indicate the beginning of some disease of the nervous system. Slight differences in size may be congenital.

Abolition of the pupil reflexes and the presence of the Argyll-Robertson pupil are especially important danger signals, but it must be remembered that the degree of the light has a great deal to do with the activity or sluggishness of these reflexes, and they should therefore be tested in a bright light so that the pupils may be afforded a chance to respond promptly if they have the power to do so.

Feebleness of the reflexes seldom signifies anything of importance, but should, nevertheless, lead the examiner to look carefully for other signs of nervous disease.

Ptosis, associated with external strabismus and some dilation of the pupil, is dependent upon paralysis of the third nerve. Its most frequent cause is syphilis. Moderate bilateral ptosis, without the other manifestations just referred to, occur in hysterical and neurasthenic conditions.

The Tongue.—A fine tremor of the protruding tongue is usually found in the early stages of general paralysis of the insane, and is considered an important sign in this disorder by neurologists. This tremor is also often seen in alcoholism.

The Gait.—Always have the applicant walk across the floor so that the gait may be observed. It may give some indication of slight hemiplegia, locomotor ataxia or paralysis agitans and lead to further investigation.

Tremor.—Ask the applicant to extend and separate the fingers widely. The motions are then apparent. If a tremor is discovered, ascertain if it is due to organic disease, alcoholism, or mere nervousness.

If the handwriting indicates a tremulous hand, find out if it is due to one of the causes already mentioned or simply to illiteracy and lack of familiarity with the pen.

Patellar Reflexes.—When the knee jerk is really absent, rejection of the risk will usually follow. Failure to obtain the patellar reflex, however, is often the fault of the applicant or the examiner. The applicant should sit with the knees loosely flexed at a blunt angle, with the muscles relaxed. When the subject is stout or heavily muscled, a better result may be obtained by having him sit on a table with the legs hanging loosely. If no contraction is obtained on striking the tendon, have the applicant lock the fingers of the hands together and give a quick pull upon them and then let go at a given signal. As the examiner gives the signal he should strike the patellar tendon at the same moment. Through this simple stratagem the applicant's mind is diverted and he relaxes the muscles of the thighs and legs which had previously been held too rigid.

The exaggerated knee-jerk may occur in the early stages of peripheral neuritis and of lesions of the spinal cord. It is also found in more advanced cases of nervous disease which would not be likely to come before an examiner for life insurance. It should be kept in mind that the knee-jerk may be somewhat exaggerated in nervous subjects and signify nothing abnormal.

Babinski's Reflex.—This important sign should be looked for when the examiner suspects some nervous disorder. Bare the applicant's foot and draw the blunt end of a pencil along the inner side of the sole from heel to toe with moderate pressure. If the great toe cocks up toward the shin, Babinski's reflex is present and may mean serious organic disease of the upper motor neurons.

Romberg's Symptom.—Test the power of the applicant to balance, by asking him to bring his feet together toe to toe and heel to heel, and to close his eyes. Inability to preserve his balance is a valuable sign in early tabes.

Occupation Cramps.—The most familiar of these is the troublesome "writer's cramp." They should not be a bar to insurance, although it is advisable to report them to the home office with full particulars after more serious disorders have been excluded by the examination.

DECREASING BIRTHRATE IN FRANCE AND GERMANY.

THE decrease in the birthrate in France has recently attracted much attention, and in Germany also the latest statistics show a marked decline in the birthrate as compared with previous years. The deathrate per 1,000 has always been and always will be a factor of prime importance in insurance work from the medical standpoint, and the birthrate of a country must also be taken into account when we review the expectation of life. This falling off in the birthrate of a country has a more profound influence on the race of people in the country

than on the actual population, and as the deathrate of the various races varies at different ages, we may see how a decreasing birthrate will inevitably affect the deathrate and also the expectancy of life of the inhabitants of the country.

In France during 1911 the deaths exceeded the births by 34,869, the number of liveborn children being 742,114, against 776,983 deaths during the same year. In England the births exceeding deaths per 10,000 during 1911 numbered 115, in Germany 141, and in Italy 112, so that in France the falling off is very marked. Although the births outnumber the deaths in Germany, still the birthrate is steadily decreasing, and this decrease has been more noticeable during the past few years. In 1876 the German birthrate was 42.6 per 1,000, whereas in 1910 it was only 30.7 per 1,000, or a fall of 11.9 per 1,000 in 34 years. The German government will shortly hold an official inquiry into the marked decrease in the birthrate, as the "population problem" will become acute if such decrease steadily advances.

As pointed out above, it has been shown that in spite of the decreasing birthrate in a country the total population goes on increasing though the "race" of the country is decreasing. Immigration explains this fact, and France may be cited as an example. In 1900 the population of France was 38,900,000, with 827,297 births; in 1908 the population had reached 39,267,000, whereas the births only numbered 791,712. Immigrants in France settle chiefly in the large cities, but the decreasing birthrate occurs in the country districts more than in the large towns; thus again we see that real race suicide is actually proved, and the proof also confirmed.

Gastric Adhesions as a Cause of Sudden Death.—G. H. Winch reports the case of a coal miner, aged 34, who, while lifting a large piece of coal into a truck, was knocked backwards against a timber prop, injuring his back and left side. He was unable to resume work. Two hours later the author found him lying on his back on a couch, with his legs drawn up. He complained of pain in the abdomen and across the back below the shoulder blades. He did not look seriously ill. His pulse was 98, his temperature 97° F., and his respirations were 20. There was no vomiting or hiccough. There were no marks of injury on the abdominal wall, which moved well with respiration, and there was no distention. On palpation there was some tenderness in the umbilical region, but no rigidity. Percussion revealed nothing abnormal, and there was no evidence of free fluid in the abdominal cavity. On his back there were some scratches and a bruise 2 inches in diameter immediately below the inferior angle of the left scapula. No ribs were broken, nor was there any injury to the spinal column. Careful examination of the circulatory, respiratory, urinary, and nervous systems revealed nothing abnormal. During the next four weeks there were no untoward symptoms or signs detected, and apparently the case was pursuing a favorable course. At the end of this period the man was very anxious to return to work, and did so against his physician's advice. In the course of his first morning at work he told his companions that he "felt better than ever before." Shortly after mid-day he suddenly fell down dead. This man had received compensation during his period of incapacity, and the question now arose, was his death due directly or indirectly to the accident or to a natural cause? By order of the coroner a post-mortem examination was made. In the abdomen small recent adhesions were found between the stomach and spleen, and between the stomach and the pancreas. The pancreas showed evidence of recent inflammation of its posterior surface opposite the spinal column. Nothing else abnormal was found in the body, though a very full and complete examination was made. The coroner's jury returned a verdict to the effect that this man's death was due to the accident. Its suddenness was probably due to a reflex stoppage of the heart, owing to the stomach dragging on the adhesions. The case brings out two points: (1) Care must be taken in dealing with accidents, even when apparently not serious, in view of the difficulties that may arise in regard to compensation. (2) It is important to keep full notes, not only of the injuries, but also of the general physical condition of the workman. For instance, in this case a thorough clinical examination was made when the patient was first seen, and this enabled one to state definitely that he had no organic disease likely to cause sudden death.—*British Medical Journal*, July 20, 1912.

Dwelling and Tuberculosis.—Beschorner says that tuberculosis is a disease that is but rarely spread by heredity, but mostly by infection from man to man. It is primarily a disease of children, the infection usually occurring in childhood, though evidences of it may not become manifest till adult age. There are two factors in the causation of tuberculosis in any person: first, diminished resistance to infection; second, exposure to infection with tubercle bacilli. The constitutional diminished resistance may be congenital, or it may be due to the action of external factors, such as environment, sickness, puberty, childbirth, bad dwelling, too much work, poor food, etc. The source of infection is found almost exclusively in the sputum of tuberculous patients, and is dangerous because of careless methods of dealing with the sputum by the consumptive. The infection may take place through the droplets coughed out by the consumptive, or indirectly through the dust containing dry sputum particles.

All these premises show the close relation that exists between the dwelling and tuberculosis, for the conditions favorable or inimical to infection depend upon the character of the dwelling and of its inhabitants. Beschorner says that tuberculosis is not a disease of "outdoors," but of closed spaces used for living or working. The morbidity of this disease is parallel to density of population, especially in the poorer classes. Of course, high rent is responsible for overcrowding, which results in nests of tubersulosis, but the intelligence of the people has very much to do with the proper or improper use of the facilities they command, however modest these may be. Tuberculosis is a disease of children, and the most dangerous condition is found where a tuberculous adult lives in an unhygienic dwelling crowded with children. Especially dangerous is the practice of having adults share their beds with several children. The duty of officials and other persons interested in the welfare of the poor is to fight such conditions and to instruct the poor in the proper utilization of their means of existence. Especially should attention be paid to instil a knowledge of hygiene into children, for only the formation of proper habits in childhood insures proper habits later.—*Zeitschrift für Versicherungsmedizin*, Vol. V, No. 4.

Book Reviews.

Diseases of the Eye. A Manual for Students and Practitioners. By J. Herbert Parsons, D. Sc., M.B., B.S., F.R.C.S., Ophthalmic Surgeon, University College Hospital; Surgeon Royal London (Moorfields) Ophthalmic Hospital; Late Ophthalmic Surgeon, Hospital for Sick Children, Great Ormond Street. Second Edition. Price $4.00 net. Philadelphia: P. Blakiston's Son & Co. 1912.

The second edition of Parsons' work is a very excellent book for the student. It constitutes a volume of 684 pages, is well printed and illustrated. The work is written by one who is abundantly qualified both from the standpoint of the pathologist, the laboratory worker, and of the clinician. It is elementary, but is well calculated to give the student a proper start in the study of ophthalmology. The text is couched in simple language, is direct, and the subject matter is presented in a very pleasing style. The author does not attempt to mention extremely rare conditions and diseases, nor does he describe the more unusual operative procedures. Section I. Anatomy and physiology, well presented. Section II. Examination of the eye. Sec. III. Diseases of the eye in logical order. This is followed by a section on errors of refraction, disorders of motility, and diseases of the adnexa of the eye. Appendices devoted to preliminary investigation of the patient, therapeutic notes, and requirements of candidates for admission into the public service (Great Britain) conclude the text. This is one of the best ophthalmic text books in English for the undergradnate in medicine.

L'Ophtalmologie du Praticien. Par le Dr. A. Cantonnet. Ophthalmologiste des Hôpitaux (Hôpital Cochin). Avec 50 figures. Price 2 fr. Paris: Librairie O. Berthier, Emile Bougault, Successeur. 1912.

This small volume of 112 pages is intended to inform the general practitioner in regard to conditions of the eyes which he should recognize and to which he might apply emergency treatment. A brief chapter on the anatomy and physiology of the eye is followed by a chapter on examination. Sixty pages are devoted to an extremely brief description of the diseases of all parts of the eye. A chapter on semeiology and a few pages on emergency surgery and bandaging complete the volume.

Die Entstehung der Kurzsichtigkeit. Von Dr. Georg Levinsohn. Privat-fur Augenheilkunde an der Universität, Berlin. Mit 3 Abbildungen im Text. Price 2.50 mark. Berlin: Verlag von S. Karger, 1912.

This monograph is devoted to a careful analysis of the various theories regarding the development of myopia and an attempt to point out the cause of the changes that take place in the establishment of this condition. The reasoning, based on original experimentation as well as on a thorough knowledge of the theories and research of others, is logical, and the conclusions are fairly convincing. The article, which forms a pamphlet of 88 pages, is a valuable contribution to our knowledge of the subject.

Manual of Surgery. By Alexis Thomson, F.R.C.S., Ed., Professor of Surgery, University of Edinburgh, Surgeon Edinburgh Royal Infirmary, and Alexander Miles, F.R.C.S., Ed., Surgeon Edinburgh Infirmary. Volume First. General Surgery. Fourth Edition, Revised and Enlarged. With 297 illustrations. Price $3.50. Edinburgh, Glasgow, and London: Henry Frowde and Hodder & Stoughton, 1912.

This is an age of concise textbooks dealing with matters medical and surgical. The book before us is the first volume of the fourth edition of a series of volumes treating of surgery on the above lines, rendering them useful to the practitioner and the student. Than Messrs. Thomson and Miles few are better adapted to attain this object, both from the standpoints of knowledge of surgery, practical and theoretical, and from literary ability. This edition differs little in essential features from the last edition, save that the general arrangement of the work has been somewhat altered. The illustrations are numerous and good, and the volume is excellent from all points of view.

Augustus Charles Bernays: A Memoir. By Thekla Bernays. Price $2.00. St. Louis: C. V. Mosby Co., 1912.

The story of Dr. Bernays' life is here told by his sister in a simple, straightforward manner that makes the book charming reading. She has wished to paint a faithful portrait of her brother, so that the outside world may see him in his true light, *i.e.* as a man of generous impulses, a strong lover of truth, a really great surgeon, and the possessor of many natural qualities which his education at the University of Heidelberg brought into active and successful play throughout his entire career. Thekla Bernays in her portrait brings out all these characteristics of her brother with remarkable fidelity.

Le Laboratoire du Praticien. Analyse Clinique. Méthodes et Procédés. Guide de Diagnostic et d'Hygiene Prophylactique des Maladies Communes, Exotiques, et Tropicales. Par Paul Gastou, Chef du Laboratoire Central et de Radiologie de l'Hôpital Saint-Louis. Avec 18 planches contenant 102 figures et photographies en Noir et Couleurs. Par Louis Niclet, Dessinateur Photographe du Laboratoire Central de l'Hôpital Saint-Louis. Premier Fascicule. Price 3 francs. Paris: A. Poinat, 1912.

This very interesting pamphlet is the first installment of a work which is to be completed by the appearance of two more parts. Gastou's object is to present a purely technical guide for the practitioner who is dependent entirely on his own resources for all his laboratory work, and in this first section he describes the general equipment required and the stains, reagents, optical appliances, etc., needed for examining the hair, skin, and cutaneous excretions in all the disorders of the epidermis and its appendages. The method in which the plan of the work is carried out is decidedly novel, tabulation being largely resorted to in order to convey information conveniently and concisely. A very large number of illustrations, many of them colored, are incorporated, and particular attention is devoted to figuring and describing the use of the dark field microscope. While not sufficiently detailed to replace the larger works on diagnostic methods, the little book is decidedly valuable, and there are probably few workers who could not glean useful hints from its pages. The succeeding sections are to be devoted to the blood, parasitic diseases, the urine, tumor diagnosis, and serological methods.

Kurzgefasste Anleitung zu den wichtigeren hygienischen Untersuchungen. Von Dr. med. Bernhard Fischer, o.o. Professor der Hygiene, Direktor des hygienischen Instituts zu Kiel. Für Studierende und Arzte, besonders an Untersuchungsämtern tätige, auch Kreisarztkandidaten und Kreisärzte. Zweite umgearbeitete und vervollständigte Auflage. Price 5.60 marks. Berlin: August Hirschwald, 1912.

This book presents as a second edition in one volume two separate guides devoted respectively to chemical and to bacteriological methods which Fischer had used in his courses at the Hygienic Institute in Kiel. It is intended to serve as an outline of the laboratory work to be done by students and also as a reference guide for workers engaged in carrying out actual work in biochemical and bacteriological fields. It is excellently adapted for both purposes, and contains an immense amount of material in condensed form. An especially praiseworthy feature is the minuteness with which all the apparatus, reagents, etc., required for each investigation are described, and the systematic use of cross references by means of which much paper and ink are saved. The sections on soil, air, water, light, and foodstuffs are noteworthy for containing many methods and details not ordinarily found in similar books.

Outlines of General and Surgical Nursing. By Winifred Frederick Lindsay, Superintendent of the Training School for Nurses of the Paradise Valley Sanitarium, National City, Cal. Loma Linda, Cal.: The College Press, 1912.

This little book contains the essentials of nursing. It could well be used to save nurses the drudgery of taking notes of lectures, and if so used would doubtless result in a better understanding of the subject. The work is divided into three parts, dealing respectively with general nursing, surgical nursing, and solutions. The book is well arranged and well printed, and the information given is judicious and reliable.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia, June 1, 1912. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger, 1912.

The present number contains a section on Hernia by W. B. Coley; one on Surgery of the Abdomen, exclusive of hernia, by J. C. A. Gerster. Then follows J. G. Clark's chapter on Gynecology containing, as usual, a most valuable summary on cancer. The section on Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Thyroid Gland, Nutrition and the Lymphatic System, is by A. Stengel; and that on Ophthalmology, by E. Jackson. This useful publication has been so often noticed here that an extended review is unnecessary.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Eightieth Annual Meeting Held at Liverpool, July 23-26, 1912.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, SIR JAMES BARR OF LIVERPOOL, IN THE CHAIR.

The meeting consisted of two distinct divisions, the political and scientific. The former is a meeting of the Representatives, the latter that of the Sections.

REPRESENTATIVE MEETINGS.

The Insurance Act.—The meeting of Representatives was held in advance and extended from the 19th to the 23rd. It was occupied chiefly with the Insurance Act trouble, and some drastic resolutions were passed after long discussions on Friday and Saturday. These came up for the report stage on Monday and were passed on to the general meeting on Tuesday afternoon, after a confirmation meeting on that morning. The first of these was the definite rupture of negotiations with Mr. Lloyd George, expressed regret that terms of cooperation with the profession had not been acceded to, and Resolved, "That the Government be informed that the association adheres to its minimum demands as formulated in the letter of February 12, and since elaborated in interviews with the Chancellor of the Exchequer."

The next resolution called on all members who had joined advisory committees in connection with the Act to withdraw from those bodies. This resolution did not apply to Ireland. As is well known, certain portions of the Insurance Act do not apply to Ireland..

The question of sanatorium benefit was considered on a different footing and was warmly discussed on Monday. Two points put forward for differentiating were (a) that it affected all the medical officers of health in the United Kingdom, and to call them out was impracticable unless absolutely necessary; (b) to prevent the sanatorium treatment being set up would be undesirable in the interest of humanity.

These questions were vigorously debated, and an additional meeting of the Representatives was held on Wednesday afternoon. Final resolutions were then adopted to submit to the general meeting, including these points and various other items. The resolutions ultimately agreed to were that

"The association calls on all practitioners to refrain from applying for, or accepting any post or office of any kind in connection with the National Health Insurance Act, except in regard to sanatorium benefit, provided it is carried on in accordance with the wishes of the association, until such time as the Government has satisfied the association that its demands will be met."

The following rider to this was approved: "That before any practitioner undertakes any work in connection with the sanatorium benefit, the conditions and duties of such appointment shall be submitted to the council for its aproval."

It was further agreed that the resolution shall not preclude medical officers of health from giving advice to public bodies in their official capacity, and that meanwhile all steps be taken to perfect the organization of the profession in the event of the Government not carrying out what is asked for. The main resolution was carried by 117 to 22 votes.

With regard to the constitution and working of tuberculosis dispensaries, it was resolved that the chief officer should be a whole-time official and confine himself to diagnosis and consultation, and that the rest of the staff should be local practitioners, the patients to be introduced by the medical attendant, the dispensary to be independent of voluntary hospitals, and local practitioners have representation on the committee. It was further considered that cases duly diagnosed and confirmed should only be treated in connection with the sanatorium, that the medical officers appointed should not be dismissed without proper notice, and that resignations of contract practice should be sent in as early as consistent with terms of engagement and the pledge. Reports and suggestions as to fees for various services, as to the organization of a public medical service, and the numerous proposals received from all parts of the Kingdom were referred to the general council for proper consideration and decision.

GENERAL MEETINGS.

Tuesday, July 23—First Day.

The annual general meeting of members took place on Tuesday afternoon, when much formal business was transacted. The outgoing president, Professor Saundby, retired from the chair, and introduced his successor, Sir James Barr, investing him with the chair and insignia of office amid the cheers of the large assembly. Professor Saundby congratulated his successor on his election, and said he was sure he would maintain the dignity of the office.

Sir James Barr, who was enthusiastically received, said he regarded it as the highest distinction to be the titular head of a society of 25,000 members of his own profession; not only so, but a position of responsibility to maintain the high tradition of the office which it would be his earnest endeavor to do. In the past year, he said, the good ship of the association has sailed through troubled waters, and though buffeted by powerful waves is nearing now a harbor of refuge. He had freely expressed his opinion of the Insurance Act and in "fairly forcible language" (laughter and cheers), but not in an official capacity, not wishing to influence those who would have the working of the Act, as he would himself have nothing to do with it. But he was pleased to see the general trend of opinion veering to his own views. He opposed the bill which had become an act on public grounds. He considered it the most gigantic fraud on a confiding public since the South Sea bubble (laughter and cheers). Both frauds were largely engineered by Members of Parliament. The earlier one was soon pricked, but already so many vested interests have been created it will be difficult to get rid of the present fraud. Just think what any intelligent being might do for the health of the nation with £30,000,000 a year! The only people likely to benefit by this fraud are a lot of officials who should be earning an honest livelihood. At present he urged you must look after the immediate requirements of the profession, which has been attacked by the monstrosity. We have long been advocating a new medical act, more needed by the public than the profession, but have been thwarted by vested interest which must be brushed aside. In conclusion he bid all a hearty welcome and wished them a happy return to their homes, adding "If I may offer you any advice, I should like to do so in the words of Norman MacLeod,

'Trust no party, sect, or faction,
Trust no leaders in the fight,
But in every word and action
Trust in God and do the right.'"

The President resumed his seat amid deafening cheers.

Dr. McLean moved and Dr. Goff seconded a vote of thanks to the retiring president, Dr. Saundby, who in response expressed confidence that their new president would foster the growth of the association.

The President-elect for 1914, Dr. Hollis of Brighton, was then introduced to the meeting.

Dr. Barrett of Melbourne invited the members to attend the Australasian Medical Congress to be held in New Zeland in 1914. This invitation was supported by Dr. F. A. Pockley of New South Wales and Dr. C. E. Todd of Adelaide.

The Chairman of Council took the chair at this point, and on the question of increasing the salary of auditors an amendment was moved by Dr. Brierley and seconded by Dr. Haddon, which led to a hot and somewhat disorderly discussion It was pointed out that £67,000 had been received in the year and spent, and more too. The freehold building, valued at £86,000, was unencumbered ten years ago, but was now security for £46,000 which had been borrowed. The speakers were interrupted as they declared the financial condition unsatisfactory and the management unbusinesslike. Much impatience was shown at the contrast drawn between the present and former state, and the question put why increase the pay of auditors when they were bankrupt. So much opposition was shown that one speaker sat down remarking that he regretted to have detained them a few minutes from their "miserable trade union work." The amendment was defeated by an overwhelming majority.

In the evening there was a very large audience at the presidential address, as many members donned their academical robes for the occasion, but it was reported that the gathering would have been still more brilliant but for an accidental miscarriage of about 200 doctorial gowns, which had been carried off to another station.

The evening's proceedings opened with the presentation to Sir James Barr of a replica of the President's

badge, but as the new President was already wearing one of these jewels, the badge was handed to Lady Barr, the only woman given a seat on the platform.

A number of Colonial and foreign guests were then presented to the President, among them representatives from San Francisco, Chicago, Paris, Berlin, Hamburg, Manilla, Yucatan, Bombay, South America, Australia, Guiana, China, Canada, Trinidad, Gibraltar.

President's Address.—After formally welcoming members and visitors to Liverpool, Sir James Barr delivered the presidential address, taking as his subject: "What Are We Doing Here? Whence Do We Come? Whither Do We Go?" This subject, he said, had been suggested to him by Henri Bergson's Huxley lecture on "Life and Consciousness." Without following any philosophic disposition as to how life and consciousness permeate matter and as to how they were started on their evolutional career by an original impetus, it occurred to him that these questions might be very appropriately asked of the medical profession: "What are we? Can we show any sufficient *raison d'être* for our existence? Are we of sufficient value to individuals and to the State to justify our continued existence as a profession? Is the world any happier for our presence? Are we really an advantage to the higher evolution of the race?" No doubt all these questions would be readily answered by them in the affirmative and the vast majority of the thinking public would also acknowledge the utility of their existence in society as it was at present constituted, though there might be some difference of opinion as to their value. During the last century or more they had been very busy trying to find out the causes of disease, the best method of their elimination, and the proper treatment of their patients. They had to a large extent succeeded. A selective death rate which was Nature's method of eliminating the unfit had been at least partly suspended by their efforts. Perhaps the majority of the medical profession would readily accept the view of Bergson "That adaptation to environment is a necessary condition of evolution. It is quite evident that a species would disappear should it fail to bend to the conditions of existence which are imposed upon it. But it is one thing to recognize that outer circumstances are forces evolution must reckon with, another to claim that they are the directing causes of evolution. This latter theory excludes absolutely the hypothesis of an original impetus—I mean an internal push that has carried life, by more and more complex form, to higher and higher destinies." How far the human intellect might succeed in unraveling many of the mysteries of life he could not at present say, but he had no doubt that in this process of evolution the human intellect would be carried to a much higher plane than that to which it had at present attained. It was their duty as medical men and as citizens of a great empire to move in the path of progress, and in every possible way to encourage the higher evolution of the race. Huxley said life as we knew it was inseparably connected with protoplasm; it was therefore important that they should see that the highest form of protoplasm, that capable of starting the individual life, the germ plasm, should be of the highest order. Natural evolution, and the evolution of the art and science of medicine, ran on different lines. Nature was lavish in the production of life and prodigal in its destruction. The process of adaptation meant elimination of the unfit. Medicine, on the other hand, had been evolved for the benefit of individuals. They had successfully interfered with the selective death rate, but they had made no serious attempt to establish a selective birth rate so as to prevent the race being carried on by the least worthy citizens. They had often joined forces with self-constituted morals in denouncing the falling birth rate, and had called out for quantity regardless of quality. They readily forgot the futility, as long ago pointed out by John Stewart Mill, lay at the basis of all morality. They were apt to forget that a high birth rate was practically always associated with a high death rate; this is Nature's method, a method which had always produced a fine race. Nature's method was too crude and barbarous, and as man rose superior to Nature and obtained more control over her laws such barbarities were replaced by more human methods. They felt compelled to preserve every human being, no matter how imperfect his intellectual and physical development. The object of their professional existence, therefore, had hitherto been the prevention and cure of disease, the alleviation of human suffering, and the prolongation of life. However, many of the higher and more intellectual minds in the medical profession had ever refused to be bound within such narrow confines. They had studied humanity, and considered how best to raise it to a higher plane and to improve the ancestral patchwork which in many families showed some scars. There was a growing consciousness among the more intellectual members of the community that the present state of matters must not be allowed to continue They must raise up a vigorous, intelligent, enterprising, self-reliant, and healthy race. If this achievement was to be accomplished they must begin with the unborn. The race must be renewed from the mentally and physically fit; the moral and physical degenerates should not be allowed to take any part in adding to the race. Above all, they must breed for intelligence. The laws of heredity should be widely taught so that those with hereditary blemishes might consider their moral responsibility of bringing children into the world. The speaker said that he knew that in expressing these views he was coming into direct conflict with some of the churches, but they forgot the saying of Jesus of Nazareth that it would have been well for this man if he had never been born. It was the duty of medical men not to pander to the selfish gratification of the individual but to point out to every one his positive and negative duties to the race. The time was now ripe for dealing with mental weaklings, and they would be effectually dealt with in all progressive nations. The advanced thought of the intelligent portion of the community would demand something more than treatment from the medical profession. This would place physiology on a higher plane than pathology. There were as yet none of their medical schools sufficiently equipped for this teaching, which was bound to come; advanced physiology and biology must lead the way. After reviewing the great advances of modern times with regard to the prevention and treatment of infectious diseases and the improvements which had been effected in sanitation and hygiene, the speaker proceeded to sketch some of the lines along which progress must proceed, and in doing this he dealt with some of the functions of the human body, taking first the nervous system. He followed out the evolution of the nervous system and the higher evolution of the intellect, looking at it both from the physical and metaphysical standpoint, and concluded that it was the higher evolution of the intellectual grades of society that were required in the present day. If the moral, intellectual, and physically well-developed members of the community were to have a fair chance of development, their energies must not be entirely dissipated in providing for the progeny of wastrels. Reproduction must proceed from the most worthy, but when the quality was good they could not have too much of a good thing. As Dr. Inge, the Dean of St. Paul, recently said, "The great menace to our civilization was not so much the stationary birth rate as the great increase among the poor and ill-fed population of their great town." Our progress might depend on the forces of civilization being able to overcome those of disintegration. During the last half century there had been not only an absolute but also a relative increase in insanity, and this increase was becoming more and more noticeable among decadent stocks. This class, although their average longevity was not great, were very prolific, and were not guided by any economic considerations. "The right to live" was not a doctrine held by any political economist, but one which had been forced upon them by the evolution of sympathy. However, they should not allow their indulgence to degenerate into license, and by gratifying their sympathies they had no moral right to leave a legacy of mental obliquity and of physical decadence to weight upon the next generation. The idea that insanity and genius were closely allied was in the main an ill-founded belief held by those who did not know what constituted a genius, or who ignorantly mistook eccentricities, or uncontrolled and ill-regulated mental activities for genius. He believed that the higher the intellectual evolution the greater the number of geniuses that were likely to be produced. There must be inherited innate qualities capable of development; a favorable environment would contribute to such development, but it could never create a genius. There was a tendency in the present day to devote more attention to the morbid manifestations of the brain than to the consideration of its evolution and development. The neuroses were studied more for their creation than for their elimination. Weird methods of study were encouraged, sensational and erotic tendencies were looked upon as natural rather than as, what they really were, degradation processes. With the elimination of tuberculosis a larger number of unstable nervous individuals reached the productive age, and hence a number of individuals were produced who early qualified for asylums. It was not any particular form of insanity which was inherited, but a neuropathic tendency which might eventuate in many forms of disease, and was often associated with disorders of the intellect. It was not alone the defects, but also the stability and

higher innate qualities of the brain which were inherited, and these higher qualities were capable of enormous development. Some of our educational authorities seemed to believe the brain to be like a piece of elastic which could be stretched out at the will of the educator, and that all individuals with equal opportunities should develop alike. They were not aware that, although brains are composed of the same ultimate elements, the quality was variable, and some brains were not even educable. Ignorance of this fact had led to the plan of affording equal opportunities to all, opportunities of which the vast majority could not make use, and it cost the country an enormous amount of money which was absolutely wasted. The feeble-minded should be dealt with in the most humane manner, either by sterilization or segregation. It was for the nation to decide which method should be adopted, but the latter would comport best with the general feeling of the community. After discussing the relation of mental activity to bodily help, and showing that mental work was more easily accomplished when there was a basis of sound health, the speaker proceeded to discuss diseases of the heart. He said that those who were fond of posing as authorities in such matters preferred waiting for the development of the disease, and were then quite prepared to give a learned disposition on the various arrythmias. When they had made a graphic illustration of the sequence of events, they vainly imagined that the problem was solved. A clear comprehension of the physiology of the heart was of much more importance for a right understanding of the working of that organ in health and disease than any amount of pathology. When it was more generally recognized that free calcium ions were essential for the continued contraction of the cardiac muscle, and that it was necessary to maintain a difference in electrical potential between the salts in the cell and those in which the muscle cell was bathed, then the methods of maintaining the healthy functions of the heart would be better understood. When it was more generally recognized that chronic degenerative lesions of the heart and arteries usually arose from causes acting on the periphery they would be better prepared to deal with such lesions when they occurred, and what was of much more importance prevent their occurrence. What was the good of measuring arterial blood pressure if one was not alive to its importance and not prepared to analyze its significance and regulate its effects? Pseudo-scientists were prone to think that when research became practical it ceased to be scientific. The speaker then called attention to recent advances in chemical biology, through which they had become acquainted with the marvelous effects which the secretions of the ductless glands had on the mental and physical attributes of the human body. In illustration, he referred to myxedema, exophthalmic goiter, diseases of the pituitary and suprarenal glands, the simple and malignant diseases of the mammary gland and the prostate, and expressed the opinion that the problem of preventing such occurrences would soon be solved. Even the surgeons were beginning to recognize that appendicitis was largely a preventable disease, and that mucous colitis, dysentery, and infantile diarrhea were more easily prevented than cured. The increased prevalence of malignant diseases of the alimentary tract was due, as was pointed out by Metchnikoff, to stagnation—a warning that everyone should take to heart. The speaker then referred to Dr. Albert Abrams as that versatile genius who had come all the way from San Francisco to do honor to this meeting of the British Medical Association,and who had taught them how best to cure intrathoracic aneurysm, and had shed light on the nature of cardiac and respiratory reflexes. Thus we had come from Hippocrates onward with a long tradition of healing, but the question was whither were they going? The path of progress which he had tried to point out would in the future devolve on such great associations as the British medical associations, which had no selfish interests to serve, but which had only the dignity of the medical profession and the welfare of the public at heart. One often heard statements to the effect that the general medical practitioner was doomed, but in the speaker's opinion the future of medicine would rest with enlightened and highly educated general practitioners, men who would look after the health of the community, who would see that mechanism of a high order was produced, and who would see that the machinery of the individual was properly lubricated and not subjected to any unnecessary friction or strain. The enlightened public would look to their medical attendants as guides, philosophers, and friends, both in health and disease. They must recognize that the outlook of the medical profession, though at present somewhat dismal, was merely a transition stage which would soon pass away.

Wednesday, July 24—Second Day.

This day the several Sections began their work, but were more sparsely attended than usual. This might be partly from their number and partly because other matters were still unsettled, and various amusements and other amenities were to the fore. A council meeting began at 9 A.M., at which hour a special service was held in St. St. Luke's Church, and another in the Roman Catholic pro-cathedral.

There was also a meeting of Catholic medical men to consider the eugenic proposals that have been put forward, and the question of the feeble-minded. This meeting adopted a resolution unreservedly condemning the sterilization of the unfit and proposing as a remedy a a partial approval of segregation. It was further recommended that the causes of mental deficiency should be studied in relation to defects of social organization. Numerous light attractions entered into the program for this day. But the chief event was

Address in Medicine.—Dr. G. A. Gibson, physician to the Royal Infirmary of Edinburgh, delivered this address, taking as his subject "The Relations of the Circulation." The orator remarked that modern physiology had its birth in the central facts of the circulation, and the many researches upon it in our epoch, the age of scientific medicine, had given ample proofs of earnestness in the search. In all the higher animals the circulation might be regarded as based upon, or concerned with, four primary groups and principles. It was based upon mechanical arrangement as the foundation for all its operations; it required chemical action, by which it was maintained and for which it provided possibilities by transference of matter; it was modified by glandular secretions, which profoundly affect its mechanism and chemical action; it was affected by nervous agencies which further profoundly influenced the performance of its functions. Many stages of being in the evoluton of the mammal, he went on, were analogous to phases of life in the development of its several representatives. It was not necessary to insist on the divergencies between infantile and adult life as regards size and weight, but it might be well to linger over certain functional deviations. The heart of the baby in relation to the weight of the body was much larger, almost double. More striking was the frequency of the heat, from 130 to 140 per minute. The whole circuit of the blood was, therefore, traversed in much less time, rather more than half. It followed that the blood was renewed in the baby's tissues with increased rapidity. The total quantity of blood, compared with body weight, was considerably larger in the baby than in the adult; and as the respiratory work, although increasing absolutely with the body's growth, was nevertheless relatively greater in early life, the absorption of oxygen was much more active than the production of carbonic acid. As a result, metabolism was extremely active within a few days of birth. As old age advanced there was a gradual weakening of the muscular and nervous apparatus with interesting external and internal changes. The metabolic activity which in youth not only met the waste, but added new material, and in adult life balanced the demand, became so impaired as to be no longer able to entirely sustain the frame. Probably every tissue participated in these retrogressive metatamorphoses, but there was no doubt that the glands, the heart, and vessels played the most important part. Were they yet in a position to decide whether the messengers which carried the impulses to the vessels and tissues were chemical or nervous? Clearly it was not through the direct action of the nervous system. It was recognized that nervous influence affected mammary secretion, but this was probably indirectly rather than directly. Simple arrest of development, antenatal or postnatal, might produce dwarfism; on the other hand, accelerated development might in both phases of existence be the first impetus towards gigantism. Whether such effects were due to an inherent tendency in the tissues, direct or indirect, no man could say. The employment of thyroid extract in myxedenia influenced blood distribution and nutritive possibilities in the most powerful manner. In youth lack of growth was common enough in both sexes. Occasionally they found children, still more frequently youths, stunted in growth, but excellent in form. The son of a medical friend of his was in his eighteenth year 1 inch below 5 feet in height; ;he had set his mind on entering Woolwich, for which his only chance was six months ahead. The family turned to the speaker in deep distress, feeling that a growth of 4 inches in six months was like adding a cubit to the stature. By employing thyroid extract that youth grew 7 inches in the six months, and as he took one of the highest places in

the examination it was clear his cerebral functions had been in no way disturbed. Similar instances, though not quite so dramatic, had been under his care; but to be quite frank, he must confess that in some of these boys and girls the treatment absolutely failed to produce an effect. As to how these powerful effects were produced, he suggested that they invoked nervous influence, consisting of waves of molecular disturbance, and these brought about changes by liberation or by inhibition. The results of these advances must enhance their hopes of even more valuable additions to their knowledge, both theoretical and practical, at a date not far distant. They opened a vista of infinite possibilities in the explanation of normal functions, the comprehension of morbid processes, the management of diseased conditions. Dr. Gibson said in conclustion: "If we may not witness in our own time the ends for which we have struggled, we have the consoling prospect that our successors will behold what we have longed to see. In the meantime let us in all our doings walk along the path of safety through accurate observation and unprejudiced investigation, wielding fearlessly the spear of Ithurial in defense of external truth."

Thursday, July 25—Third Day.

The proceedings of this day were very diversified. The Sections began their sittings, providing the scientific and practical work, while several events and entertainments afforded lighter enjoyment.

Temperance Breakfast.—The day opened with the breakfast given by the National Temperance League, at which there was a large attendance, and interesting views were expressed by Sir James Barr, Professor Mott, and others. The chair was taken by Mr. Alexander Guthrie, who said these breakfasts afforded an opportunity of bringing before people who more than most had the power of influencing their fellows in regard to alcohol and its dangers. Abstainers or not, they most recognize what a factor alcohol was in the national life and how extrèmely important it was for right views to be formed about it. He spoke of the state of Liverpool in this respect twenty years ago, and the steady administration of the laws which had led to a diminution in the city of the number of public houses by 800. Still much remained to be done and it behooved them to continue the fight against this great contributory curse of crime, disease, and misery. Sir James Barr said he practically never prescribed alcohol now, for people were too ready to prescribe for themselves too much. He knew of no disease from which patients would get on better with than without it. People were more temperate now than ten years ago, as might be noticed at public dinners. Professor F. J. Mott attributed much intemperance to the conditions of the poor. The problem was to improve their housing and other unhygienic environment. He would segregate the chronic inebriate as a danger to the community. The state should prevent disease and no better way of coping with it existed than to reduce intemperance.

Address in Surgery.—Mr. F. T. Paul, consulting surgeon to the Royal Infirmary, said that he preferred to record his experience rather than extend his observations in a more general address. Accordingly he took as his subject "Personal Experiences in the Surgery of the Large Bowel," but limiting his remarks to procedures which have been advanced of late years and those in which he has had considerable personal experience, chiefly the following operations: Colotomy, short-circuiting, colectomy and excision of the rectum. These operations were needed to meet very different pathological conditions, though most of them ultimately presented the clinical feature of obstruction. Cancer accounted for more than all the rest put together, and the greater part of his remarks were concerned with cases of malignant disease. It was of paramount importance that surgeons should familiarize themselves with the characters of the different kinds of cancer met with in the various parts of the body, as so much depended upon the behavior to be expected from each kind. This was especially true of intestinal cancer, for in no other part of the body was there a greater variation in the degree of malignancy than in the bowel. The speaker expressed himself as quite convinced that cancer of the bowel might undergo spontaneous cure, and he rested this assertion upon the following grounds: (1) For over thirty years he had been removing these growths and submitting them to personal microscopical investigation. He was, therefore, very familiar with their nature and appearance. (2) Many cases having the minute structure of cancer had not recurred, though known to have been removed with an insufficient margin of safety. (3) Malignant disease of the bowel was rarely removed during the early stage, yet the percentage of cures was remarkably good. (4) The duration of life after colotomy for inoperable cancer of the bowel was often prolonged compared with that in other inoperable cancer cases, while a proportion of the cases seen, handled, and passed as malignant got well and the tumor disappeared. He then proceeded to discuss the three varieties of carcinoma of the bowel, the large soft fungating or encephaloid type, the small hard cirrhous type, and the infiltrating or colloid type. In considering the misconceptions regarding cancer, he said that some seemed to forget that "cirrhous" and "encephaloid" were merely terms of clinical or macroscopical significance, convenient when properly used, but otherwise very misleading. The really important misconception, however, concerned the relative malignancy of the three varieties of cancer. The encephaloid type had been regarded as the most malignant; the colloid as being intermediate and the cirrhous as the most benign. This arrangement was entirely wrong and out of accord with clinical experience. The colloid was the most malignant type, the ring stricture came next, and the fungating type was the least. It was a clinical fact of considerable importance that the up-growing forms of cancer were essentially less malignant than the down-growing, ulcerating, and shrinking type. After describing the histology of bowel cancer with the aid of illustrations he said that the most common sites for the fungating growth were the rectum and cecum, though it often occurred in the sigmoid, and occasionally any other part of the large bowel. Colloid cancer chiefly selected the rectum, and ring stricture the sigmoid, though neither were limited to these regions. If the surgeon when operating took the pathological details into consideration, they would often influence him considerably in his decision as to the nature and extent of the operation. Thus, if the growth was one of the fungating type, recognized by its softness, bulk, situation, character of gland infection, and so forth, he would on the one hand feel justified in removing the tumor without necessarily interfering with any tissue much beyond the visibly affected area; or, on the other hand, if the risk to life seemed too great to allow of this being done, he would be encouraged to hope for a reasonably long period of relief by short-cutting or colotomy. If the tumor proved to be massive and solid, and especially if there was evident glistening gland or peritoneal infection, or if the growth was in the rectum and could be felt as an abrupt hard edged ulcer, then the case was one of colloid cancer, and the outlook would be discouraging. In the case of ring strictures, always easily recognizable, the indication was to excise more widely than one used to think necessary, and to remember that in this type of growth they had the best reason for following up the path of lymphatic infection. These rules for guidance had come as the result of his practical experience, and he wished to say a few words regarding the clinical details which bore upon the same point. The first great line of demarkation in the clinical arrangement of these cases was the presence or absence of complete obstruction at the time they came under a surgeon's observation. In his earlier experiences complete obstruction with fecal vomiting and meteorism were regarded as necessary preliminaries to an application for surgical aid. So constantly fatal were all surgical operations for intestinal obstruction in those days that one thought very little of the objections to an artificial anus. Now, should any such feeling of objection encourage one to risk life for the sake of at once accomplishing a neat and clean surgical procedure? He felt sure that whenever there was complete obstruction in the colon a preliminary colotomy was by far the safest course in all those cases in which any form of internal strangulation could be excluded. The one class of case in which he always wished to make an exception was when the obstruction was actually at the ileo-cecal valve, and it was necessary to open the small bowel, and usually there were favorable prospects for short-circuiting in this situation. If, however, paresis and collapse had already supervened an artificial anus was imperative. Unfortunately, they were still without means for recognizing cancer of the bowel in its really early stages, except when it was located low down in the rectum. An *x*-ray screen view of the behavior of the bismuth meal was useful if its limitations were recognized, but in no circumstances could it indicate either the extent or the malignancy of the growth, nor could the ready passage of the bismuth meal be regarded as a contra-indication to operation. If the diseases was within reach of the sigmoidoscope this instrument might be of considerable assistance in the diagnosis of growths situated in the pelvic colon. If the site of the obstruction was not rendered apparent by other means, the behavior of an anema might give useful information. When it was in the sigmoid region the bowel was irritable, and rarely tolerated

more than half a pint, which was rapidly returned. When higher up much more might be injected and retained. In all cases of complete obstruction of the large bowel, whether diagnosed by exploration or otherwise, and in which strangulation was absent, he advised colotomy in the first instance in preference to an internal operation. The only drawback to a colotomy under such circumstances was the increased time occupied before the whole proceeding could be completed; but since the one operation would very often prove fatal, and the two or three very rarely so, their patients would infinitely prefer the latter course if they understood the whole circumstance. In deciding as to where the bowel should be opened he thought that as a temporary proceeding one should always decide on a right lumbar operation. This was safe, satisfactory, and out of the way of the future abdominal section. He had tried this procedure on many occasions, and the more experience he had with it the more favorably it appealed to him. Whenever a colotomy was expected to be permanent, and the seat of the obstruction permitted, the left iliac operation should be selected. The operation was free *per se* from danger, and yielded the best results obtainable. Transverse colotomy was practically unnecessary and very rarely desirable. Right lumbar colotomy, on the other hand, had a wide field for useful application as a means of affording temporary relief in cases of complete obstruction of the colon below the cecum, and was a valuable method of treating certain cases of inflammation and ulceration of the colon. He had done colotomy upon sixty-eight patients in private practice during the past ten years. In forty-four of these there was no obstruction, or it was chronic in type, and all recovered. In twenty-four cases acute obstruction was present, and nine deaths occurred. These were mostly in old people with vomitting (often fecal), meteorism, and collapse. It was interesting to note that eighteen of the cases of complete obstruction were met with during the first period of five years, and accounted for seven of the nine deaths, while in the remaining period there were only six cases with two deaths, showing that practitioners were recognizing the importance of earlier surgical treatment. It was also interesting to note that cancer of the rectum was the primary trouble in half the cases, and that his statement as to the long duration of life after colotomy for cancer was borne out. In regard to internal operations, after the obstruction had been relieved for a sufficient length of time to bear this procedure, the malignant growths were excised if possible; otherwise short-circuiting was the only available improvement upon colotomy. Tuberculous disease of the cecum might be excised, but the results were not satisfactory. For tuberculous ulceration lower down in the colon and rectum when severe the best surgical treatment was colotomy. Fibrous stricture varied much in their extent and position, and excision, sort-circuiting, or colotomy might be employed in accordance with the special conditions present in each case. The speaker said that he probably did a smaller proportion of short-circuiting operations than many other surgeons, and that in regard to this operation there were two points upon which it seemed to him that emphasis ought to be laid. One was that in cases of obstruction in which paresis of the bowel was present short-circuiting might fail to relieve, while an external fecal fistula would be successful. He, therefore, did not recommend short-circuiting operations in the presence of any severe form of obstruction such as was likely to be fatal without immediate relief. The other point was that he had had the best success when he had cut out of circuit the smallest possible amount of bowel. He, therefore usually short-circuited just around the growth or other obstruction. During the last ten years he had employed this operation in twelve of his private patients without mortality. In eight of these cases he had joined the ileum to the colon and in four colon to colon. However good the results of short-circuiting or colotomy might be, one must always wish to excise a malignant tumor of the bowel whenever circumstances permitted. The cecum and the sigmoid were the most favorable and fortunately the most frequent situations for tumors of the colon. The cecal operation was certainly the more extensive of the two, but on the whole these cases had done better, chiefly in the way of the cure being more permanent. Increasing experience had encouraged him to undertake the major operation in more cases of cancer of the colon, and in less cases of cancer of the rectum. His table of cases showed that he had undertaken colectomy on eighteen private patients during the last ten years. Only one died; this was a patient in which he had attempted primary suture and which otherwise would have been favorable. The remaining seventeen were done by the glass tube operation, and all recovered, though some of them were advanced in years. Of these seventeen cases three were non-malignant, and fourteen cancer. Of the latter eight are still living and not known to have recurrence; two have died from apoplexy and four have died from recurrent growth at 2½, 3½, 3½ and 7 years, respectively. In considering growths of the rectum he considered only those which called for excision. He had already expressed the view that a well-planned colotomy was not inconsistent with health and reasonable comfort, or with the pursuit of ordinary occupations. If this were more generally admitted some lives that were risked and lost would be saved. All cases of advanced cancer of the rectum, incurable fibrous stricture from syphilis or other cause, some recto-vesical fistulae, and some tuberculous or other ulcerations should be treated by colotomy. In regard to a preliminary colotomy it not only lessened the risk of operation, but it expedited healing, and he considered that for these good reasons it should be used with more frequency. A point in which his experience did not coincide with that of most surgeons was that regarding the value of retaining any portion of healthy bowel that might be situated below the disease. He had long come to the conclusion that an attempt to retain the anus with more or less of the lower end of the rectum was bad practice. However carefully one adapted the parts the resulting anus was rarely better, and often not so good as one placed high up at the top portion of the wound behind the sacrum. To be successful in this operation one must not only operate well and carry out the subsequent treatment with care, but one must also recognize that this was one of those serious undertakings for which a wide discretion must be exercised in the selection of suitable cases. From the age of 55 onward selection should be rigidly practiced. Operations for cancer of the rectum were, on the whole, less favorable than those on the colon. During the past ten years he excised the rectum for cancer in twenty-eight private patients. Two deaths occurred, one the double route operation in a male, the other a high resection in a female. Neither were good subjects. Of the twenty-eight thirteen were still living—1, 1, 2, 2½, 3, 3¼, 3¼, 5, 6, 6, 7½, 9, and 10 years. Twelve died from recurrence. The average duration was 13 months. One died from other cause. The speaker described in detail the various operations which he had used, calling special attention to the differences in technique in operating upon the male and the female in rectal excisions and to the value of retaining the bone, and illustrated his descriptions by means of pictures.

In the afternoon there was a choice occupation. A number of members took a trip up the river and were entertained to tea by the Mayor of Wallasey (Dr. J. A. Aldershaw. Another party visited the garden suburb at Waventree, where they inspected the houses being rapidly erected. Many are already occupied. The visitors were welcomed by two of the directors of the copartnership company which is developing the estate.

Annual Dinner.—In the evening came the annual dinner, held in the Philharmonic Hall, and generally pronounced to be the most brilliant entertainment of the meeting. Besides the profession, the guests included the civic notabilities of Liverpool, its culture and its commerce, the assembly numbering nearly 350. Fall palms adorned the orchestral platform, flanked with beautiful exotic plants.

Dr. Macdonald (Chairman of Council) proposed the toast of the "City and University of Liverpool," very appropriately united, for it happens that Lord Derby is Lord Mayor of the one and Chancellor of the other. His Lordship, in responding, said both corporation and university deserved appreciation at the hands of their profession, for Liverpool was the pioneer which set up a school for tropical medicine at her university and London had followed suit. It was initiated by thatgreat Liverpool citizen, Sir Alfred Jones, who by establishing it had given his name an undying recollection and brought credit to his native city. He wished more people devoted themselves to the welfare of their localities. There were diseases in municipal bodies too deeply seated for party politics to cure. He hoped the time would come when all would do all they could to secure the health and thereby the happiness of those who lived about them.

The Bishop of Liverpool (Dr. Chavasse), whose direct ancestors for 200 years have been connected with the medical profession, proposed the toast of "The Association," and said he was sure the public outside desired they should receive a living wage, as did colliers. The idea of this noble and beneficent profession being on half-pay, starved or straitened, was abhorrent to every Britisher.

Dr. E. J. MacLean, Chairman of the Representative Body, responded and referred to the great growth of the

association since the last meeting in Liverpool. He said the dominating body was the meeting of representatives. The public might misunderstand their constitution, as they sometimes did that of the public. "Breaking Off Negotiations," of which so much was said, did not mean boycotting insurance for all time, but that conditions must be in the interests of the whole public as much as in their own. The duties we are asked to perform must be properly defined as to both normal benefit and extras, and the question is not one of the pocket only. The "Guests" and the "President" were proposed and enthusiastically honored.

AMERICAN SOCIETY OF TROPICAL MEDICINE.

Ninth Annual Meeting, held at Atlantic City, N. J., June 3, 1912.

The Eradication of Malaria.—Dr. Joseph H. White of New Orleans, La., said that malaria possessed a wider interest than any other of the tropical diseases in the United States, and particularly in the South. There had been countless deaths charged to malaria that did not belong to it. Many physicians, through ignorance, had signed death certificates giving malaria as the cause, when it was absolutely foreign to the disease, while others had knowingly charged up such things as syphilis to malaria. He thought that the morbidity of malaria, rather than the mortality, was the question of importance, particularly in the South. The morbidity was not over-estimated, but the mortality was largely so. He observed that the filling up of our country with inhabitants had done much toward accomplishing the desired result in many parts of the Northern and Middle States, practically obliterating malaria; but that there were many places where this was not so; therefore, the remedy would have to be applied in a palliative way, by excluding the mosquitoes from the houses, draining small pools of water near, and oiling those that could not be drained, using for that purpose an oil that had been devised by Colonel Gorgas, and which was composed of resin, caustic silver and some other things that were cheaper and more effective than oil. Dr. White felt that the main point was the elimination of the swamps; and that the State and Nation, as well as the citizens, must be appealed to. He asked whether national drainage was not as important as national irrigation; irrigation led only to public wealth, while drainage led to both health and wealth. He observed that if malaria were not removed from the South, the negro race would be the only one that could live there.

Dr. M. P. Ravenal of Madison, Wis., said that as a boy he was given to understand that malaria was invariably fatal, and that for a white man to spend the night across the river from Charleston—his home—in St. Andrew's Parish, was equal to shooting himself. It was the habit all through the South for the people to leave their plantations about the fifteenth day of May, and not return to them until after the first frost had fallen. It was his belief that only the plantation negro was immune from malaria, as he had seen negroes from the foothills brought down to the phosphate fields die like flies of that disease. He felt that the important factor in the obliteration of malaria was the proper draining of the swamps, and that if this were done thoroughly it would be unnecessary to even screen the houses. He observed that the so-called poor whites of the South—who were generally accused of laziness—were as energetic as any people when they were well; but that malaria, together with hookworm, had been a primary factor in taking away their ambition. With the drainage of the malarial districts and the cultivation of areas of land, there had been an enormous material development, so that the public health question was one of great importance to this country from that standpoint, as well as from the racial one.

Dr. B. F. Royer of Harrisburg, Pa., said that malarial fever cut very little figure in Pennsylvania, because it was a reportable disease, and a placard was put on each premise where it existed. It had formerly been common for physicians to speak of indefinite fevers as a touch of malaria, but the reporting of the disease had done away with that loose method of diagnosis. Physicians could no longer call typhoid fever malaria, since they both were reportable, and the State Laboratory was available in which to make the tests. He said the State furnished to the physicians all over the State a little shipping outfit which held three glass slides, on which they could send smears to the laboratory.

Dr. E. H. Hume of Changsha, China, said that in central China, where there was a great deal of rice raised, there were none of the anopheles within hundreds of miles, but in other sections of rice country there were crowds of them. He observed that the present studies seemed to indicate that the presence of anopheles had something to do with the kinds of fish, etc., contained in certain waters, and that they hoped within the next few years to find the solution of that problem. Malaria was so scattered in China that it was being worked out as a problem of great importance, he said.

Dr. Wm. H. Jeffreys of Shanghai, China, said that it was his opinion that the drainage of swamps on a big scale would have to be done by the State or Congress, as individual enterprise had never done a great deal in that direction; this had been shown by the attitude the people of Maryland had taken toward draining their swamps when the State had offered to pay two-thirds of the cost, but had not made the drainage compulsory.

Comparative Observation on the Biological Characteristics of Spirochæta Pallida and Spirachæta Pertenuis.—Dr. Henry J. Nichols of Washington, D. C., said that the differences in morphology were slight, and that the same was true of the cultural characters that had been so far observed. No specific antibodies had been demonstrated, but distinct differences occurred in experimental lesions in the rabbit, and the action of salvarsan was distinctive. He felt that there was great need for investigation along the lines of spirochæta pallida and spirochæta pertenuis.

Dr. Creighton Wellman of New Orleans said that to work out some of the relationships by means of complement deviation, or by other means, was very much worth while. He stated that he had discovered pertenuis and published his paper dealing with that discovery a few weeks after Castiglianti's discovery; and that it, therefore, only served to confirm his, but that he had worked his own out and sent the paper away long before he saw Castiglianti's paper. Dr. Wellman differed with Castiglianti in some points, and did not believe the two diseases should be united, but that they should be considered entirely distinct. He felt that if one once saw a case of yaws and one of syphilis, he would get them so settled in his mind that they could not be mistaken for each other. It was his opinion that more scientific care should be given to solving the question of the tropical diseases.

Dr. Nichols said that one of the drawbacks to that sort of work in tropical diseases was the scarcity of laboratories—properly fitted up—in the tropics. While they might see many cases of yaws in the tropics, yet they might not have the facilities to work with; but in the temperate zone they probably had the laboratories, though not the cases.

Cultural Studies of Malarial Parasites.—Dr. Creighton Wellman of New Orleans presented this report for Dr. C. C. Bass, who had been sent on a scientific expedition to Central America, by the Tulane University of Tropical Medicine, of New Orleans, in order to better study malaria. Dr. Bass had succeeded in cultivating the malarial parasites and following out the entire cycle of schizogeny, not only in culture but in transplants. The work had been begun some months ago, and he had succeeded in keeping the malarial parasites alive for seven weeks. In an announcement in the *Journal of the American Medical Association* a short time ago Dr. Bass had described the method of his work. Dr. Wellman thought that this discovery of Dr. Bass's was worthy to stand beside the former discovery that the mosquito was the host of the malarial parasite.

A Simple Method of Differentiating Disease Bearing Insects.—Dr. C. S. Ludlow of Washington, D. C., discussed the general external resemblances and differences between ticks and bedbugs, lice, and fleas. She thought that wing venation offered a good means of differentiating groups of flies, as the family was always indicated, and sometimes the genus was made evident by that means. She observed that the classification of the mosquito was in almost inextricable confusion.

Dr. Creighton Wellman of New Orleans said that in no other group of arthropods were there so many new species suggested as in the case of the mosquitoes. He did not approve of the attempt to name animals and insects by people who were entomologists, and not specialists. He suggested that when one is going to work with a species of mosquito, he should first find out just what it is by sending specimens of it to someone especially working with mosquitoes; and this, also, should be done with any kind of insect. It was his idea that students in tropical medicine could help greatly in the filling up of the gaps and the gathering of the data referring to the life history of almost all of the insects. He said that the best way of clearing up the habitat of the tsetse fly was based on the fact that a peculiar degree of shade and humidity was necessary for its reproduction. The clearing away of the timber in the fly belt had been efficacious,

because those flies wandered only a few yards from the belts. Dr. Wellman observed that it was his opinion that the collecting of exact data, and the getting of facts, from which to draw a deduction with regard to the extermination of the mosquito, would be of more benefit at the present stage of the problem than the making of ingenious suggestions and hypotheses, many of which were not based on facts.

Dr. Joseph Goldberger of Washington, D. C., said that he thought there was too much tendency in all branches of zoology to a very broad, superficial study, and that the number of species and genera was appalling. He felt the time had come when intensive study was needed rather than a layer of poorly recorded facts. More about the life histories of the animal was needed; and instead of rushing madly after new species those that were already known should be carefully studied.

Dr. Ludlow said that the study of flies was surrounded with more difficulties than was usually recognized; that the anopheles were shy, so that many persons were unable to find them, even where they existed.

Bacteriemic Nature of Leprosy.—Dr. Damaso Rivas of Philadelphia, Pa., said that the work was based upon the fact that *Bacillus lepræ* was easily found in the blood of cases of leprosy. The method consisted in collecting 0.1 to 1.0 cc. of the patient's blood, from the tip of the finger or toe (free from lesions) in about 5 to 20 cc. of a 2 per cent. solution of acetic acid, in which the erythrocytes were dissolved. The mixture was centrifuged for about fifteen minutes, and the sediment examined for alcohol acid-fast bacilli. He observed that the method of staining was one usually followed in the examination for tubercle bacilli, the sediment being spread on a slide, dried, fixed, stained with carbol fuchsin, decolorized with 30 per cent. hydrochloric-acid solution in 95 per cent. alcohol, and counterstained with methylene blue. In his original paper, he gave plates illustrating the *Bacillus lepræ* found free in typical aggregation or scattered, as well as in the form of lepra cells (that is, endothelial cells or lymphocytes filled with the bacillus); also a few bacilli phagocytized by the lymphocytes were shown as evidence that the *Bacillus lepræ* was found in the circulating blood. He remarked that that method was advantageous in demonstrating the bacteriemic nature of leprosy, and also as a means of diagnosis of the disease.

Early Diagnosis of Filariasis.—Dr. Damaso Rivas of Philadelphia, Pa., said that his method was based upon finding the microfilaria in the blood in the early stage of the disease, and that to do this one should collect from 0.1 to 1.0 cc. of the blood, from the finger, in about 5 to 10 cc. of 2 per cent. acetic-acid solution, in which the erythrocytes are dissolved. After shaking, the mixture should be centrifuged for about 5 minutes, when the sediment might be examined. Either fresh cover-glass, or dried and stained preparations should be made from the sediment. With the acetic-acid method, he considered it immaterial at which hour of the day or night the examination was made, and stated that if the case was positive the microfilaria would be found in the sediment. Four comparative tables were given in the paper, and the advantages of the acetic-acid method over the common, fresh-blood, cover-glass preparation were summarized as follows: (1) Microfilaria of *F. nocturna* or *F. loa* are found in the peripheral blood at all hours of the day or night. In cases of *F. nocturna*, of course, the greater number is found at night; while in *F. loa* the greater number is found in the day. (2) The periodicity of microfilaria in the peripheral blood is related to the relative number of embryos circulating from the blood, and not to an absolute absence of them from the capillaries. (3) The acetic-acid method is of especial advantage in the early diagnosis of filariasis. By it the microfilaria can be demonstrated in the blood as soon as the adult filaria reaches maturity and begins to discharge its embryos, which, in all probability, takes place years before the obstructive symptoms of filariasis are manifested.

Dr. Henry J. Nichols of Washington, D. C., said that there should be more careful investigation of the tropical diseases; that there had been too much tendency in this branch of research to tell some wonderful story about a disease not clearly known, except to a few. He declared that while it was true that the *Filaria diurna* was in the circulating blood in the daytime, it was also there at night. He said that he had observed several cases of patients who were watchmen, and that at the end of a certain period of time their periodicity had not changed; they still had more filaria at night than in the daytime.

Summary of the Literature on the Etiology of Beriberi.—Dr. John M. Swan of Rochester, N. Y., suggested the following definition: Beriberi is a disease of metabolism, characterized pathologically by a polyneuritis, and clinically by an acute stage resembling an acute infection, by a stage associated with marked edema, and by a stage of polyneuritis and paralysis; and due to a diet of which uncured rice forms the principal element.

Investigation of Louisiana Rice with Reference to the Etiology of Beriberi.—Dr. Creighton Wellman and Dr. C. C. Bass of New Orleans, La., presented a paper on this topic, in which they detailed a series of experiments with chickens for the purpose of finding out whether Louisiana rice would have the same effect as the polished rice from the Orient. Two samples of Louisiana rice were obtained—one was secured at the mill after the chaff had been removed, and was designated "unpolished rice;" the other lot was obtained when the rice was ready for the market, except that the final coat of glucose and talcum had not been applied, and was designated "polished rice." Marked nerve symptoms appeared after 17 to 23 days in the fowls fed exclusively upon the polished rice; but the unpolished rice did not produce the disease. It was also stated that the unpolished rice included with a general diet cured the disease; that a diet of pure cane sugar would produce beriberi more rapidly even than the polished rice, and that cornstarch would also produce it.

The Public Health Problems in Connection with Beriberi.—Dr. R. H. Creel of Ellis Island, N. Y., said that beriberi in the United States had been confined to sporadic outbreaks in various parts, and had not assumed public health proportions. He asserted that the cause of beriberi was not known, but that the great epidemicity of the disease during the last thirty years had been coincident with the increased output of steam-milled, or polished rice. He observed that beriberi in Manila was on the increase, except in Government-controlled institutions, where it had practically been suppressed. It was Dr. Creel's idea that the prevention of beriberi lay in the Government's controlling the milling process of rice, and passing a rice law similar to the corn law that Italy had. He suggested a fine and the confiscation of polished rice, whether imported or for sale locally.

Dr. R. L. Wilbur of San Francisco, Cal., said that he felt that a distinction should be made between polyneuritis due to inanition and that due to infectious microorganisms. He observed that if beriberi was entirely due to food, one would expect to get much more widely scattered cases, rather than epidemics. He told of an instance in which the officers of a ship, as well as the sailors, had all come down within the space of a few days with beriberi, some of them even dying from the disease. All of these cases could not have been attributed to the same food supply.

Dr John M. Swan of Rochester, N. Y., said that in the City of Canton, which was supposed to be outside the beriberi zone, there had been a very severe outbreak of the disease in 1907, in the military camps. Out of 6,000 troops there were 600 cases of beriberi, with a mortality of 20 per cent. He thought that the use of polished rice was a preeminent factor in the etiology of beriberi, and said that that was the consensus of opinion of the members of the Far Eastern Association of Tropical Medicine at the meeting held in Hong Kong, China, last February. He remarked that while it was formerly thought that beriberi was contagious, yet of later years, owing to careful investigations, the cases had not been isolated, and no indications of contagion had been seen. Dr. Swan favored the adoption of measures by the different Governments that would control the production of polished rice.

Dr. W. H. Jeffreys of Shanghai, China, thought that the polished rice theory was hard to accept, because of the fact that the disease apparently did appear epidemically. He stated that Shanghai and Hong Kong were the places in China where beriberi was most pronounced. In spite of the fact that they had paid a very high price for rice for St. Luke's Hospital, beriberi had broken out constantly, but when dried beans were added to the diet there was very much less trouble from the disease.

Dr. Judson Daland of Philadelphia, Pa., said that ten years ago beriberi was considered of bacterial origin, but that now the polished rice theory seemed to be conclusive, though care should be used in diagnosing from the standpoint of etiology. He stated that experiments had shown that animals fed on polished rice lost weight, became paralyzed, and eventually died; but if unpolished rice and other articles of diet were added this was prevented. He asserted that beriberi occurred in individuals whose food supply depended entirely on the carbohydrates contained in rice, and from which the phosphorus was subtracted, thus producing certain unknown changes resulting in polyneutritis, or a condition which closely resembled the neuritis, caused by inanition. He declared that rice which contained less than 0.4 per cent. of phosphorus pentoxide should be looked upon as a prejudice to health, and that

those disposing of it should be dealt with accordingly.

Dr. Henry J. Nichols of Washington, D. C., said that he was much interested in the points brought out by Dr. Wellman, especially as to the fact that beriberi could be produced by cornstarch, molasses or cane sugar, but he had no sympathy with Dr. Wilbur's suggestion as to the infectious theory. He asserted that beriberi, as they had it in the East, was as fully established in connection with polished rice as scurvy was with the lack of fresh vegetables.

Dr. Creel stated that while the Java possessions contained a population of 250,000, 90,000 of whom were fed entirely on red rice, yet there were only nine cases of beriberi, one to every 10,000; whereas, in those persons fed on white rice, there were 280 per every 10,000. This seemed to him most conclusive.

Dr. Swan of Rochester, N. Y., said that he had never been convinced as to the infectious nature of beriberi, and that while many persons thought beriberi and pellagra similar he was of the opinion that beriberi was more like scurvy.

Dr. Wellman said that he felt that the whole condition of beriberi was rather more unsettled in his mind than it had been before he began the experiments, and that while most of the evidence gotten together pointed to the rice theory, yet he disagreed with Dr. Nichols in the opinion that no other theory should be considered. There were still many facts to be explained, such as certain cases he had found in the islands of the Gulf of Guam, whose symptoms and clinical diagnosis were undistinguishable from beriberi, and yet no rice had been eaten by the patients; and again, cases in which what appeared to be polished rice had been eaten, and beriberi was in much less evidence than in the other vicinity. He said that the attacking of young, strong adults was not clear to his mind; and so far as the phosphorus content of the rice was concerned, there were also objections to this theory.

Some Investigations in Leprosy.—Dr. Creighton Wellman of New Orleans said he had become interested in the therapy of leprosy some years before, and he had tried salvarsan in a series of experiments in cases of leprosy in California; the clinical findings in these cases he had presented at the last meeting of the American Society of Tropical Medicine. Judging from some cases which he had had some time back, he considered salvarsan of great value in the early treatment of the disease. He stated that Dr. Duval and himself had come to the conclusion, from some experiments they had worked out together, that the chromogenic acid-fast bacillus was the etiological factor in leprosy. He had isolated from a leprous lesion a slowly-growing non-chromogenic bacillus, which he had cultivated in a medium made from human placenta. He had also found this placenta medium very valuable in cultivating the *Bacillus tuberculosis* from lesions and exudates.

Dr. Judson Daland of Philadelphia, Pa., said that if it turned out to be true that Dr. Wellman had found the etiological factor in leprosy, it would be an extraordinary step forward in the study of that disease; and that any statement made by Dr. Wellman's co-worker, Dr. Duval, would be of great interest to those working along the same line.

Dr. Wellman said that he believed the non-chromogenic slow-grower and the Clegg chromogenic rapid-grower to be distinct from each other, and that he hoped to be able to complete his investigations by the next meeting, and have something more definite to detail.

Gangosa.—Dr. G. L. Angeny of Philadelphia, Pa., said that gangosa had been prevalent in Guam for more than a century, was destructive, and showed ulcerations of the oral and nasal mucous membranes. He stated that it began as an ulcer of the nose, mouth or pharyngeal wall, with no pain or other symptoms, the patient often not even being aware of its existence until the ulcer had reached considerable size, when the process would advance until the bone was destroyed. The duration varied from a few months to many years, he said; but the general tendency was to recover, and when death occurred, it was usually due to some intercurrent disease. He observed that the etiology of the disease was obscure, and while there were three theories advanced none of them had been verified.

Dr. Wellman said that in the Naval Hospital, at Mare Island, California, he had studied half a dozen cases of so-called gangosa, but to him all the cases looked very much like lupus. One case puzzled him considerably, because of the involvement of the hard palate. He told of a diphtheroid bacillus which Dr. Garger had isolated, believing it to be closely identified with gangosa. By the use of autogenous vaccines Dr. Garger had effected apparent cures of some of the worst cases. Dr. Wellman said that the fact that these diphtheroids were so easily isolated from any sore throat made it probable that the bacillus of Garger was the etiological factor.

Specimens of Flukes from China.—Dr. W. H. Jeffreys of Shanghai, China, showed two specimens of flukes from China and remarked that one variety was common in China, Formosa, the Philippines, and Malay; it was called the endemicus, and was the less harmful. The patient, from whom the specimen was taken, was a typical case, and had some 545 specimens in the gall-bladder and bile ducts. He stated that the particular characteristics of the endemicus were length and amount of segmentation. The other fluke, he remarked, was common in China, India, and Formosa; and, as it had been thoroughly described by various writers, was well known.

A Malarial Hotbed within Sight of the National Capital.—Dr. Thomas W. Jackson of Ft. Washington, Md., called attention to the continued existence of malaria within fifteen miles of Washington, in spite of the fact of the sanitary conditions had been greatly improved and the mosquitos largely exterminated. He felt that quinine prophylaxis had been disappointing; in fact, a failure, and he considered it a false and dangerous doctrine.

Dr. Damaso Rivas of Philadelphia, Pa., said that he had had great difficulty in getting patients to take the quinine faithfully, and that it was most efficacious to give it one hour after the temperature had begun to fall, because at that time the parasite was very young and was apt to take more quinine then than later. He advised doses of about ½ to 7½ grains, always diluted with hydrochloric acid, and felt that the recurrences of malaria were unquestionably due to taking the quinine at the wrong time.

Dr. William Kraus of Memphis, Tenn., said that about a year ago he had had a patient referred to him for the administration of salvarsan. He found that the patient had malaria, of the pseudo-autumnal form. The result of the administration of the salvarsan was the disappearance of the malarial parasites, and since that time there had been no further recurrence of the disease. He thought this remedy might have a marked effect on malaria.

Dr. Charles Craig of Washington, D. C., said that he did not think quinine prophylaxis could be compared for a moment with mosquito extermination. He told of an experience he had had at Fort Stoltzenburg, which had the worst record of any post of the United States Army. They had tried every means to do away with malaria, when finally he ordered the patients to come to the hospital twice a week, where they were forced to take the quinine in the presence of an officer. When this was done, the numerical ratio went down over fifty per cent.

Dr. John M. Swan of Rochester, N. Y., said that he had formerly taught his students that it was necessary to administer quinine to malarial patients for two years after their clinical recovery. He said his reason for doing this was because he had accepted the theory that recurrences or relapses were due to parthenogenesis. There had always seemed to him to be a parallel between malaria and syphilis, because of the necessity for continuing the treatment for a long time after clinical manifestations were gotten rid of, in order to prevent a relapse or recurrence of the disease. Dr. Swan stated that it was possible for a person with the parasites in the blood to present a perfectly normal blood picture until he had a relapse.

Dr. Joseph H. White of New Orleans, La., said that he thought the destruction of the mosquito and the use of quinine prophylaxis were equally necessary in the eradication of malaria.

Dr. Jackson said that he did not condemn quinine prophylaxis generally, but that he thought it should not be substituted for mosquito destruction. He observed that his principal reason for being opposed to the indiscriminate use of quinine was that it vitiated the blood diagnosis. He felt that no definite rule should be laid down as to the length of time over which the medicine should be given, though he felt that the period was often made too short, and that the only sure guide was the repeated examination of the blood.

The Society adopted a resolution endorsing the creation of a United States commission for the study and prevention of malaria, and calling upon Congress to appropriate funds for this purpose

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Edward R. Stitt, Washington, D. C.; *First Vice-President*, Dr. Richard P. Strong, Manila, P. I.; *Second Vice-President*, Dr. Creighton Wellman, New Orleans, La.; *Secretary*, Dr. John M. Swan, Rochester, N. Y.; *Assistant Secretary*, Dr. Allen J. Smith, Philadelphia, Pa.; *Treasurer*, Dr. C. Lincoln Furbush, Philadelphia, Pa.

The next meeting will be held in Washington, D. C., in May, 1913.

THE DIAGNOSTIC SIGNIFICANCE OF ABNORMALLY QUICK FATIGUE (APOCAMNOSIS) OF THE ORBICULARIS ORIS MUSCLE.

By J. LEONARD CORNING, M.D., LL.D.,

NEW YORK.

THE symptoms due to irritative or destructive lesions involving the functional efficiency of the facial nerve, directly or indirectly, wholly or in part, have been explicitly dealt with by numerous writers. That the muscles supplied by this nerve may be affected by spasm; that they may be palsied by neural, nuclear, or cerebral involvement; that they may be the seat of atrophy—these are facts so long authenticated that they have become the merest text-book commonplaces. It is not to manifestations so intrusively obvious that the writer would direct the attention of those who care to read. Briefly, his endeavor will be to show that the kinetic competency of the facial muscles, and notably that of the orbicularis oris, stands in a somewhat exceptional relation—if one may so phrase it—to the functional adequacy of the related cortical neurons, so that the presence of conditions tending to lessen the energy of the cerebrum as a whole and of its centrifugal (motor) functions in particular must needs express itself rather more decisively and promptly in the muscles of the face than in other parts of the neuromuscular mechanism.

In arriving at this inference the writer has been influenced by the following considerations:

That the embouchure of those who play upon wind instruments—hautbois, clarionet, bassoon, flute, etc—is injuriously affected by overindulgence in alcoholic beverages of all kinds. A similar, though perhaps less considerable detriment follows prolonged abuse of tobacco. These sequences are more pronounced in or after middle age; they are especially evident when attempts are made to play the high notes softly, and they become distressingly apparent during protracted playing demanding nicety of modulation, as in solo work.

This lack of endurance of the orbicularis is unquestionably due to impairment of innervation, to diminished vigor of the voluntary nervous mechanism, and not to any fault of the muscle itself, which indeed is overdeveloped in players upon wind instruments. A further proof of this is disclosed by the fact that the exhibition of certain chemicals which exert a stimulating action on the central nervous system, diminish or entirely remove, for the time being at least, all subjective or objective evidences of muscular fatigue. Adequately to appreciate why the inertness of the muscle which we are here considering should so injuriously affect the artistic efforts of the player, it must be borne in mind that upon the orbicularis oris devolves a leading rôle in the embouchure of wind instruments, their correct modulation and articulation being indeed, in an immediate and special sense, dependent upon the strength, endurance, and coordinative adjustments of that muscle.

A significant fact bearing on the thesis which it is the writer's purpose to maintain, is that while in players upon wind instruments the orbicularis oris muscle, and in fact, all the expressional muscles of the face, may as the result of abuse of tobacco and alcohol temporarily part with a considerable amount of endurance, the other muscles of the body—save in extreme cases—remain comparatively unaffected.

Nor is this lack of endurance of the orbicularis oris a sequence of toxic influences only. It is disclosed in conditions of debility involving the organism as a whole and the cerebrospinal axis in particular, and it appeares, moreover, fairly early as a rather significant sign in general paralysis of the insane.

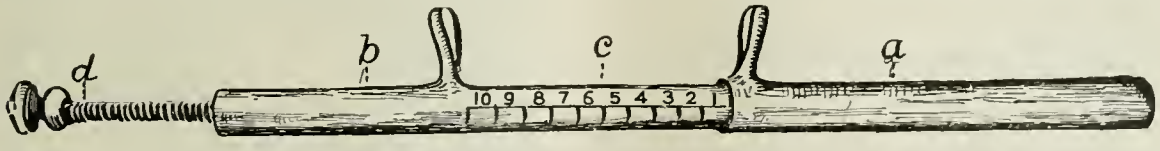

Fig. 1.—Appliance for testing the fatigue phenomenon of the orbicularis oris muscle

The writer has also encountered it in arteriopathic dementia, in which it assumed, as it were, a kind of primacy among the more general symptoms of motor weakness. Neurasthenia of a severe type, accompanied by marked bodily enfeeblement, may likewise disclose this incompetency of the orbicularis.

It is evident, from what has been said, that to bring out the fatigue phenomenon which we are here discussing, some simple apparatus is indispensable. The appliance pictured below (Fig. 1) possesses the merit of being at once simple and practical. Designed by the writer some time ago, it has seemed, after numerous trials, to have thoroughly demonstrated its efficiency. Two tubes, the one four (Fig. 1, a), the other six and a half inches long (b), slide freely, the one within the other. The shorter is the outer, the longer, the inner tube. At the inner end of the outer tube is a short hook-like arm, in length about three-quarters of an inch. Four inches from the inner end

of the inner tube a similar arm is soldered on. Between these arms a scale (c) about three inches long has been engraved on the inner tube. This scale has been divided into degrees of a quarter of an inch, each degree being numbered. The outer end of each of these tubes is closed, and a long

Fig. 2.—Showing the lateral expansion of the orbicularis oris upon the introduction of the instrument .

spiral spring, filling out the lumen formed by the two tubes, extends from end to end of the latter. From this disposition it is evident that the spring, impinging against the outer closed ends of each tube, tends to resist the approximation of the two arms. Again, it is clear that such resistance may be increased or diminished by the rotation of the screw (d) at the outer end of the inner tube, since the inner end of this screw presses against the end of the spiral spring. The practical application of the device is so apparent that but few words will be required to help to its intelligent manipulation. (1) Having, by the aid of finger and thumb, pressed together the two projecting arms, the latter are introduced into the mouth and allowed to expand until impinging against the corners of the mouth, they cause the orbicularis muscle to relax fully in a horizontal direction (Fig. 2). The subject should be cautioned not to oppose this dilatation, and the tension of the spring should be so regulated by means of the screw as to insure complete lateral expansion of the muscle, but without stretching it. (2) He should then be told to contract the muscle as much as possible, as though about to whistle (Fig. 3). The length of this contraction will be shown by the scale and should be carefully noted. This exercise of the muscle should be repeated at regular intervals, the observer making note of the number of contractions executed before a falling off in the amplitude of the latter takes place. Such decrease in the extent of the contractions can promptly be determined by consulting the graduated scale. (3) With the first appearance of this decline in the length and vigor of the contractions, the observer will begin to count anew, making note of the number of contractions, until the subject having reached the limit of his capacity, they (the contractions) cease absolutely. It is evident that without lavish expenditure of ingenuity apparatus may be devised—revolving cylinder, pneumatic attachments, pen, etc.—which will graphically register the decline in amplitude of the contractions of the orbicularis consequent upon fatigue. Unfortunately mechanism of the kind is neither easy to carry about nor easy to manipulate. Those, however, who are hospitable to sophistication of the sort may, perhaps, care to try it.

In pathological cases, the relatively small number of contractions preceding the first evidence of fatigue (diminution of the amplitude of the contraction) and the rapid fall in the extent of the contraction thereafter are the characteristic features.

The following simple formula is submitted in deference to those who may care for such things: Let *a* represent the number of contractions *preceding* the first appearance of diminution in the amplitude of the contractions; *b* the number of voluntary contractions evocable *thereafter,* and *x* the degrees of fatigue which it is sought to determine. We shall then have $\frac{b}{a} = x$.

A comparison with the average results obtainable under normal conditions will serve to disclose the diagnostic significance of the test.

In the ultimate estimate, however, it is not to be forgotten that the endurance of the orbicularis is usually greater in men than in women and children; that it is greater in active, muscular individuals than

Fig. 3.—Showing partial contraction of the orbicularis oris.

in those who lead sedentary lives, and that it is greatest of all in those who play upon wind instruments. Again, it is noteworthy that when the exercise of the muscle is continued much beyond the first evidence of fatigue, a sensation referred to the orbicularis, and variously described as "heaviness"

or "numbness" is apt to cause complaint. Even in persons of robust health this may sometimes happen after fifteen or twenty contractions.

The opinion that the fatigue phenomenon thus disclosed is not merely muscular but corresponds in large measure with exhaustion of the cortical neurons concerned in the innervation of the orbicularis has already been advanced. To the evidence previously adduced in favor of that opinion may be added the fact that even when the ring muscle of the mouth is exercised to the point at which voluntary action is no longer possible, it may still be made to contract by the application of the faradic current.

The foregoing facts, though significant in themselves, become doubly intelligible in view of the special relationship existing between the underlying mechanism of the emotions and the expressional apparatus of the face. How the facial muscles responding automatically to the stir within disclose with unmistakable signals much of the affective life is realized by all. That the character and intensity of the emotions themselves are influenced in an immediate and surprising degree by physiological conditions is, however, not always so promptly thought of, save in the more blatantly obvious relation of cause and effect disclosed by the use of intoxicants, or as one finds it revealed in the course of certain well-known visceral derangements.

A brief glance at the physical basis of emotion, as now understood, will help to a rational explanation of the emotional exaltation following cerebral stimulation or depression, and to the framing of a concept—however faulty in the present state of knowledge—of the genesis of emotion under normal conditions as well.

Originating from the parietal lobe more especially, but likewise, though less abundantly, from all parts of the cortex, certain fibers descend to distribute themselves in the red nucleus. On their way thither these fibers graze the thalamus and assist in the formation of the tegmentum. These fibers (described by M. and Mme. Déjerine) constitute, it seems plausible to assume, the upper portion of the emotional motor system. Thence downwards (from the red nucleus) the route is continued, according to some investigators (Probst, Held, Collier, Buzzard), by way of the rubrospinal bundle of Monakow, which, arising on the ventral side of the red nucleus, decussates in the crossway of Forel with the corresponding fasciculus from the opposite side, to pursue its course down the medulla spinalis (in the vicinity of the lateral tracts) as far as the sacral region. It is this rubrospinal bundle of Monakow which connects the opposite red nucleus with the ventral horn of the spinal cord.

Incidentally it may be remarked that the close proximity of the corticorubral fibers to the thalamus is probably reponsible for the opinion so frequently advanced that the thalamus is to be looked upon as the structural basis of expressional movements. It requires, indeed, but moderate familiarity with the anatomy of the region which we are discussing to realize that a lesion causing a solution of the "emotional motor fibers" at that point may likewise involve the thalamus, so that a just relation of cause and effect may be difficult to determine.

The purpose subserved by this corticorubrospinal system in the genesis of emotion may be conceived to be somewhat as follows: A sensation, visual, auditory, or what not, or a precept or an idea gives rise in the cortex to an impulse which is transmitted downward by way of the corticorubral fibers to the red nucleus. Thence it pursues its course by way of Monakow's rubrospinal tract to the motor cells of the lowest level, and so through the nerves to the muscles. Parenthetically it may be observed that the expressional apparatus of the face alone concerns us for present purposes. It is held that it is the muscle sensations—or largely these—following contraction of the muscles of expression, which, on reaching the cortex by way of the sensory tracts, give rise to the emotion, the tone of the latter being, however, influenced by the combinations of the muscular sensations among themselves and by the addition of vasomotor sensations as well.

In view of what has already been said, it is clear that the whole mechanism of the emotions is essentially involuntary, and that in this respect they (the emotions) resemble the instincts. While this is true, it is not to be forgotten—and this is of importance in connection with the objects of the present writing—that the muscles of the face whose purpose is rather expressional than dynamical are likewise under the dominion of the will through the medium of the Rolandic-motor system, with whose physiology all are no doubt familiar. It is, thanks to the presence of this arrangement, that the counterfeit expression of the actor is made possible, who, were he deprived of this ability, would be entirely beholding to the reflex (psychical) or involuntary play of the muscles of expression under the incitement of genuine emotion, a condition which for obvious reasons is not always to be realized on the stage.

The physical bases of the two modes of expression then are evidently independent of each other.

Certain well-known clinical observations, which, while serving to show the independence of the two systems of expression—the voluntary and the involuntary—also reveal the important part played by the thalamic region in the mechanism of expression may at this portion of the argument be cited with advantage. When, let us say, a patient has a lesion of the right Rolandic area, he smiles *reflexly* in response to a jest on both sides of the face; but a *voluntary* or "assumed" smile occurs on the right side only, volitional action on the left side being paralyzed. When, however, a lesion of one optic thalamus, say the right, is present, a jest evokes a smile on the right side only; and yet, when told to assume a smile, the muscles of both sides of the face are seen to act. Here, then, it would seem, is reasonable proof that the physical bases of the two modes of expression are substantially independent.

Yet, granting this autonomy of each system, the conclusion seems justified, nay, almost inevitable, that any general cause, acting, let us say, through the circulation upon the involuntary mechanism of expression, must exercise a corresponding influence upon the voluntary mechanism as well. The general distribution throughout much of the cortical area of the neurons of the involuntary emotional system, and the consequent intermingling more or less, of the neurons of both systems suggest this. Again, but more directly to the purpose, we have the experimental data afforded by the wind instrument players already alluded to. In these may be found coincident depression of the neuromuscular system of expression, voluntary and involuntary alike, the dual phenomenon being immediately traceable to a single general cause, such as intoxication by alcohol or nicotine.

There would seem, therefore, theoretical as well

as empirical sanction for the view that the degree of endurance of the orbicularis oris muscle, as disclosed by the voluntary exercise already described, may in a very real sense represent the condition not only of voluntary, but of involuntary innervation as well. From these considerations it follows, that in conditions of mental depression there should be diminution more or less of the endurance of the orbicularis when voluntarily exercised. And in fact, practical tests prove this to be the case.
